conformational change triggers the downstream effects of the hormone. A single hormone molecule, in forming a hormonereceptor complex, activates a catalyst that produces many molecules of second messenger, so the receptor serves not only as a signal transducer but also as a signal amplifier. The signal may be further amplified by a signaling cascade, a series of steps in which a catalyst activates a catalyst, resulting in very large amplifications of the original signal. A cascade of this type occurs in the regulation of glycogen synthesis and breakdown by epinephrine (see Fig. 12-7). Epinephrine activates (through its receptor) adenylyl cyclase, which produces many molecules of cAMP for each molecule of receptorbound hormone. Cyclic AMP in turn activates cAMPdependent protein kinase (protein kinase A), which activates glycogen phosphorylase b kinase, which activates glycogen phosphorylase b. The result is signal amplification: one epinephrine molecule causes the production of many thousands or millions of molecules of glucose 1-phosphate from glycogen. Water-insoluble hormones (steroid, retinoid, and thyroid hormones) readily pass through the plasma membrane of their target cells to reach their receptor proteins in the nucleus (Fig. 23-3). With this class of hormones, the hormone-receptor complex itself carries the message: it interacts with DNA to alter the expression of specific genes, changing the enzyme complement of the cell and thereby changing cellular metabolism (see Fig. 12-30). Hormones that act through plasma membrane receptors generally trigger very rapid physiological or biochemical responses. Just seconds after the adrenal medulla secretes epinephrine into the bloodstream, skeletal muscle responds by accelerating the breakdown of glycogen. By contrast, the thyroid hormones and the sex (steroid) hormones promote maximal responses in their target tissues only after hours or even days. These differences in response time correspond to different modes of action. In general, the fast-acting

23.1 Hormones: Diverse Structures for Diverse Functions

933 hormones lead to a change in the activity of one or more preexisting enzymes in the cell, by allosteric mechanisms or covalent modification. The slower-acting hormones generally alter gene expression, resulting in the synthesis of more (upregulation) or less (downregulation) of the regulated protein(s). Hormones Are Chemically Diverse Mammals have several classes of hormones, distinguishable by their chemical

structures and their modes of action (Table 23-1). Peptide, catecholamine, and eicosanoid hormones act from outside the target cell via cell surface receptors. Steroid, vitamin D, retinoid, and thyroid hormones enter the cell and act through nuclear receptors. Nitric oxide (a gas) also enters the cell but activates a cytosolic enzyme, guanylyl cyclase (see Fig. 12-20). Hormones can also be classified by the way they get from their point of release to their target tissue. Endocrine (from the Greek endon, “within,” and krinein, “to release”) hormones are released into the blood and carried to target cells throughout the body (insulin and glucagon are examples). Paracrine hormones are released into the extracellular space and diffuse to neighboring target cells (the eicosanoid hormones are of this type). Autocrine hormones affect the same cell that releases them, binding to receptors on the cell surface. Mammals are hardly unique in possessing hormonal signaling systems. Insects and nematode worms have highly developed systems for hormonal regulation with fundamental mechanisms similar to those in mammals. Plants, too, use hormonal signals to coordinate the activities of their tissues (Chapter 12). The study of hormone action is not as advanced in plants as in animals, but we do know that some mechanisms are shared. To illustrate the structural diversity and range of action of mammalian hormones, we consider representative examples of each major class listed in Table 23-1.

Class	Type	Example
Synthetic path	Mode of action	Peptide
Insulin, glucagon	Proteolytic processing of prohormone	Catecholamine
Epinephrine	From tyrosine	Plasma membrane receptors; second messengers
Eicosanoid	PGE, From arachidonate (20:4 fatty acid)	Steroid
Testosterone	From cholesterol	Vitamin D
1 α ,25-Dihydroxyvitamin D ₃	From cholesterol	Nuclear receptors; transcriptional
Retinoid	Retinoic acid	From vitamin A
Thyroid	Triiodothyronine (T ₃)	From Tyr in thyroglobulin
Nitric oxide	Nitric oxide	From arginine + Os
Cytosolic receptor (guanylyl cyclase) and second messenger (cGMP)		

934 Hormonal Regulation and Integration of Mammalian Metabolism

Peptide Hormones Peptide hormones may have from 3 to 200 or more amino acid residues. They include the pancreatic hormones insulin, glucagon, and somatostatin; the parathyroid hormone calcitonin; and all the hormones of the hypothalamus and pituitary (described below). These hormones are synthesized on ribosomes in the form of longer precursor proteins (prohormones), then packaged into secretory vesicles and proteolytically cleaved to form the active peptides. Insulin is a small protein (M, 5,800) with two polypeptide chains, A and B, joined by two disulfide bonds. It is synthesized in the pancreas as an inactive single-chain precursor, preproinsulin (Fig. 23-4), with an amino-terminal "signal sequence" that directs its passage into secretory vesicles. (Signal sequences are discussed in Chapter 27; see Fig. 27-38.) Proteolytic removal of the signal sequence and formation of three disulfide bonds produces proinsulin, which is stored in secretory granules (membrane vesicles filled with protein synthesized in the endoplasmic reticulum) in pancreatic β cells. When blood glucose is elevated sufficiently to trigger insulin secretion, Preproinsulin Signal sequence Proinsulin + H₃N—C—C peptide Mature insulin B chain

FIGURE 23-4 Insulin. Mature insulin is formed from its larger precursor preproinsulin by proteolytic processing. Removal of a 23 amino acid segment (the signal sequence) at the amino terminus of preproinsulin and formation of three disulfide bonds produces proinsulin. Further proteolytic cuts remove the C peptide from proinsulin to produce mature insulin, composed of A and B chains. The amino acid sequence of bovine insulin is shown in Figure 3-24. Pro-opiomelanocortin (POMC) gene = Aa DNA | 5' m 3' MRNA | + HN | -COOSignal | | | peptide y-MSH ACTH B-Lipotropin a-MSH CLIP y-Lipotropin 6-Endorphin 1 4 B-MSH Met-enkephalin

FIGURE 23-5 Proteolytic processing of the pro-opiomelanocortin (POMC) precursor. The initial gene product of the POMC gene is a long polypeptide that undergoes cleavage by a series of specific proteases to produce ACTH, B- and y-lipotropin, a-, B-, and y-MSH (melanocystestimulating hormone, or melanocortin), CLIP (corticotropin-like intermediary peptide), B-endorphin, and Met-enkephalin. The points of cleavage are paired basic residues, Arg-Lys, Lys-Arg, or Lys-Lys. proinsulin is converted to active insulin by specific proteases, which cleave two peptide bonds to form the

mature insulin molecule and C peptide, which are released into the blood by exocytosis. In some cases, prohormone proteins, rather than yielding a single peptide hormone, produce several active hormones. Pro-opiomelanocortin (POMC) is a spectacular example of multiple hormones encoded by a single gene. The POMC gene encodes a large polypeptide that is progressively carved up into at least nine biologically active peptides (Fig. 23-5). In many peptide hormones the terminal residues are modified, as in TRH (Fig. 23-2). The concentration of peptide hormones in secretory granules is so high that the vesicle contents are virtually crystalline; when the contents are released by exocytosis, a large amount of hormone is released suddenly. The capillaries that serve peptide-producing endocrine glands are fenestrated (punctuated with tiny holes or “windows”), so the hormone molecules readily enter the bloodstream for transport to target cells elsewhere. As noted earlier, all peptide hormones act by binding to receptors in the plasma membrane. They cause the generation of a second messenger in the cytosol, which changes the activity of an intracellular enzyme, thereby altering the cell’s metabolism.

Catecholamine Hormones

The water-soluble compounds epinephrine (adrenaline) and norepinephrine (noradrenaline) are catecholamines, named for the structurally related compound catechol. They are synthesized from tyrosine (see Fig. 22-31).

Tyrosine —> L-Dopa —» Dopamine —> Norepinephrine —> Epinephrine

Catecholamines produced in the brain and in other neural tissues function as neurotransmitters, but epinephrine and norepinephrine are also hormones, synthesized and secreted by the adrenal glands. Like the peptide hormones, catecholamines are highly concentrated in secretory vesicles and released by exocytosis, and they act through surface receptors to generate intracellular second messengers. They mediate a wide variety of physiological responses to acute stress (see Table 23-6).

Eicosanoid Hormones The eicosanoid hormones (prostaglandins, thromboxanes, and leukotrienes) are derived from the 20-carbon polyunsaturated fatty acid arachidonate. Phospholipids | Arachidonate (20:4) Prostaglandins Thromboxanes Leukotrienes

Unlike the hormones described above, they are not synthesized in advance and stored; they are produced, when needed, from arachidonate enzymatically released from membrane phospholipids by phospholipase A₂. The enzymes of the pathway leading to prostaglandins and thromboxanes are very widely distributed in mammalian tissues; most cells can produce these hormone signals, and cells of many tissues can respond to them through specific plasma membrane receptors. The eicosanoid hormones are paracrine hormones, secreted into the interstitial fluid (not primarily into the blood) and acting on nearby cells. Prostaglandins promote the contraction of smooth muscle, including that of the intestine and uterus (and can therefore be used medically to induce labor). They also mediate pain and inflammation in all tissues. Many antiinflammatory drugs act by inhibiting steps in the prostaglandin synthetic pathway (see Fig. 21-15). Thromboxanes regulate platelet function and therefore blood clotting (see Fig. 6-39). Leukotrienes LTC₄ and LTD₄ act through plasma membrane receptors to stimulate contraction of smooth muscle in the intestine, pulmonary airways, and trachea. They are mediators of anaphylaxis, an immune overresponse that can include airway constriction, altered heartbeat, shock, and sometimes death.

E Steroid Hormones The steroid hormones (adrenocortical hormones and sex hormones) are synthesized from cholesterol in several endocrine tissues.

23.1 Hormones: Diverse Structures for Diverse Functions

935 Cholesterol v Progesterone pe k? Cortisol Testosterone (glucocorticoid) 4 | Aldosterone (mineralocorticoid)

Estradiol (sex hormones) They travel to their target cells through the bloodstream, bound to carrier proteins. More than 50 corticosteroid hormones are produced in the adrenal cortex by reactions that remove the side chain from the D ring of cholesterol and introduce oxygen to form keto and hydroxyl groups. Many of these reactions involve cytochrome P-450 enzymes (see Box 21-1). The corticosteroids are of two general types, defined by their actions. Glucocorticoids (such as cortisol) primarily affect the metabolism of carbohydrates; mineralocorticoids (such as aldosterone) regulate the concentrations of electrolytes (K^+ , Na^+ , Ca^{2+} , Cl^-) in the blood. Androgens (such as testosterone) and estrogens (such as estradiol; see Fig. 10-19) are synthesized in the testes and ovaries. They affect sexual development, sexual behavior, and a variety of other reproductive and nonreproductive functions. Their synthesis also involves cytochrome P-450 enzymes that cleave the side chain of cholesterol and introduce oxygen atoms. All steroid hormones act through nuclear receptors to change the level of expression of specific genes (see Fig. 12-30). They can also have more rapid effects, mediated by receptors in the plasma membrane.

Vitamin D Hormone Calcitriol (1 α ,25-dihydroxycalcitriol) is produced from vitamin D by enzyme-catalyzed hydroxylation in the liver and kidneys (see Fig. 10-20a). Vitamin D is obtained in the diet or by photolysis of 7-dehydrocholesterol in skin exposed to sunlight. 7-Dehydrocholesterol $\xrightarrow{\text{UV light}}$ Vitamin D₃ (cholecalciferol) $\xrightarrow{25\text{-Hydroxycholecalciferol}}$ 1 α ,25-Dihydroxycalcitriol

Calcitriol works in concert with parathyroid hormone in Ca^{2+} homeostasis, regulating $[Ca^{2+}]$ in the blood and the balance between Ca^{2+} deposition and Ca^{2+} mobilization from bone. Acting through nuclear receptors, calcitriol activates the synthesis of an intestinal Ca^{2+} -binding protein essential for uptake of dietary Ca^{2+} . Inadequate dietary vitamin D or defects in the biosynthesis of calcitriol result in serious diseases such as rickets, in which bones are weak and malformed (see Fig. 10—20b). E

936 Hormonal Regulation and Integration of Mammalian

Metabolism Retinoid Hormones Retinoids are potent hormones that regulate the growth, survival, and differentiation of cells via nuclear retinoid receptors. The prohormone retinol is synthesized from B-carotene, primarily in liver (see Fig. 10-21), and many tissues convert retinol to the hormone retinoic acid (RA). B-Carotene | Vitamin A, (retinol) | Retinoic acid All tissues are retinoid targets, as all cell types have at least one form of nuclear retinoid receptor. In adults, the most significant targets include cornea, skin, epithelia of the lungs and trachea, and the immune system, in all of which there is continuing replacement of cells. RA regulates the synthesis of proteins essential for growth or differentiation. Excessive vitamin A (the precursor to retinoid hormones) can cause birth defects, and pregnant women are advised not to use the retinoid creams that have been developed for treatment of severe acne.

E Thyroid Hormones The thyroid hormones T₄ (thyroxine) and T₃ (triiodothyronine) are synthesized from the precursor protein thyroglobulin (M, 660,000). Up to 20 Tyr residues in thyroglobulin are enzymatically iodinated in the thyroid gland, then two iodotyrosine residues condense to form the precursor to thyroxine. When needed, thyroxine is released by proteolysis. Condensation of monoiodotyrosine with diiodothyronine produces T₄, which is also an active hormone released by proteolysis. Thyroglobulin - Tyr | Thyroglobulin - Tyr- 1 (iodinated Tyr residues) | proteolysis Thyroxine (T₄), triiodothyronine (T₃) The thyroid hormones act through nuclear receptors to stimulate energy-yielding metabolism, especially in liver and muscle, by increasing the expression of genes encoding key catabolic enzymes.

Nitric Oxide (NO) Nitric oxide is a relatively stable free radical synthesized from molecular oxygen and the guanidinium nitrogen of arginine (see Fig. 22-33) in a reaction catalyzed by NO synthase. Arginine + 1/2 NADPH + 2H₂O → NO + citrulline + 1/2 NADP⁺ This enzyme is found in many tissues and cell types: neurons, macrophages, hepatocytes, myocytes of smooth muscle, endothelial cells of the blood vessels, and epithelial cells of the kidney. NO acts near its point of release, entering the target cell and activating the cytosolic enzyme guanylyl cyclase, which catalyzes the formation of the second messenger cGMP (see Fig. 12-20). A cGMP-dependent protein kinase mediates the effects of NO by phosphorylating key proteins

and altering their activities. For example, phosphorylation of contractile proteins in the smooth muscle surrounding blood vessels relaxes the muscle, thereby lowering blood pressure.

Hormone Release Is Regulated by a Hierarchy of Neuronal and Hormonal Signals

The changing levels of specific hormones regulate specific cellular processes, but what regulates the level of each hormone? The brief answer is that the central nervous system receives input from many internal and external sensors—signals about danger, hunger, dietary intake, blood composition and pressure, for example— and orchestrates the production of appropriate hormonal signals by the endocrine tissues. For a more complete answer, we must look at the hormone-producing systems of the human body and some of their functional interrelationships. Figure 23-6 shows the anatomic location of the major endocrine glands in humans, and Figure 23-7 represents the “chain of command” in the hormonal signaling hierarchy. The hypothalamus, a small region of »———

abi R (releasing factors) First targets the brain (Fig. 23-8), is the coordination center of the endocrine system; it receives and integrates messages from the central nervous system. In response to these messages, the hypothalamus produces regulatory hormones (releasing factors) that pass directly to the nearby pituitary gland through special blood vessels and neurons that connect the two glands (Fig. 23-8b). The pituitary gland has two functionally distinct parts. The posterior pituitary contains the axonal endings of many neurons that originate in the hypothalamus. These neurons produce the short peptide hormones oxytocin and vasopressin (Fig. 23-9), which move down the axon to the nerve endings in the pituitary, where they are stored in secretory granules to await the signal for their release. The anterior pituitary responds to hypothalamic hormones carried in the blood, producing tropic hormones, or tropins (from the Greek tropos, "turn"). These relatively long polypeptides activate the next rank of endocrine glands (Fig. 23-7), which includes the adrenal cortex, thyroid gland, ovaries, and testes. These glands in turn secrete their specific hormones, which are carried in the bloodstream to the target tissues. For example, corticotropin-releasing hormone secreted from the hypothalamus stimulates the anterior pituitary to release ACTH, which travels through the blood to the zona fasciculata of the adrenal cortex and triggers the release of cortisol. Cortisol, the ultimate hormone in this cascade, acts through its receptor in many types of target cells to alter their metabolism. In hepatocytes, one effect of cortisol is to increase the rate of gluconeogenesis.

23.1 Hormones: Diverse Structures for Diverse Functions 937

FIGURE 23-7 Some of the major endocrine hormones and their target tissues. Signals originating in the central nervous system (top) pass via a series of relays to the ultimate target tissues (bottom). In addition to the systems shown, the thymus, pineal gland, and groups of cells in the gastrointestinal tract secrete hormones. Dashed lines represent neuronal connections.

Thyroxine Insulin, corticosterone, (T4), triiodo- ari Testosterone glucagon, Epinephrine aldosterone thyronine (T3) somatostatin

Hormonal cascades such as those responsible for the release of cortisol and epinephrine result in large amplifications of the initial signal and allow exquisite fine-tuning of the output of the ultimate hormone (Fig. 23-10). At each level in the cascade, a small signal elicits a larger response. For example, the initial electrical signal to the hypothalamus results in the release of a few nanograms of corticotropin-releasing hormone, which elicits the release of a few micrograms of corticotropin. Corticotropin acts on the adrenal cortex to cause the release of milligrams of cortisol, for an overall amplification of at least a millionfold. At each level of a hormonal cascade, feedback inhibition of earlier steps in the cascade is possible; an unnecessarily elevated level of the ultimate hormone or of an intermediate hormone inhibits the release of earlier hormones in the cascade. These feedback mechanisms accomplish the same end as those that limit the output of a biosynthetic pathway (compare Fig. 23-10 with Fig. 22-37): a product is synthesized (or released) only until the necessary concentration is reached.

SUMMARY 23.1 Hormones: Diverse Structures for Diverse Functions > Hormones are chemical messengers secreted by certain tissues into the blood or interstitial fluid, serving to regulate the activity of other cells or tissues.

In some cases, such as insulin, a single hormone is produced by proteolytic cleavages; in others, such as POMC, several distinct hormones are produced by cleavage of a single prohormone. > Hormones are regulated by a hierarchy of interactions between the brain and endocrine glands: nerve impulses stimulate the hypothalamus to send specific hormones to the pituitary gland, thus stimulating (or inhibiting) the release of tropic **FIGURE 23-9 Two hormones of the posterior pituitary gland.** The carboxyl-terminal residue of both peptides is glycineamide, —NH—CH₂—CONH₂; (as noted in Fig. 23-2, amidation of the carboxyl

terminus is common in short peptide hormones). These two hormones, identical in all but two residues (shaded light red), have very different biological effects. Oxytocin acts on the smooth muscle of the uterus and mammary gland, causing uterine contractions during labor and promoting milk release during lactation. Vasopressin (also called antidiuretic hormone) increases water reabsorption in the kidney and promotes the constriction of blood vessels, thereby increasing blood pressure.

FIGURE 23-10 Cascade of hormone release following central nervous system input to the hypothalamus. Solid black arrows indicate hormone production and release; broken black arrows indicate the action of hormones on target tissues. In each endocrine tissue along the pathway, a stimulus from the level above is received, amplified, and transduced into the release of the next hormone in the cascade. The cascade is sensitive to regulation at several levels through feedback inhibition (thin, dashed arrows) by the ultimate hormone (in this case, cortisol). The product herefore regulates its own production, as in feedback inhibition of biosynthetic pathways within a single cell.

hormones. The anterior pituitary hormones in turn stimulate other endocrine glands (thyroid, adrenals, pancreas) to secrete their characteristic hormones, which in turn stimulate specific target tissues.

> Hormonal cascades, in which catalysts activate catalysts, amplify the initial stimulus by several orders of magnitude, often in a very short time (seconds).

23.2 Tissue-Specific Metabolism: The Division of Labor Each tissue of the human body has a specialized function, reflected in its anatomy and metabolic activity (Fig. 23-11). Skeletal muscle allows directed motion; adipose tissue stores and distributes energy in the form

23.2 Tissue-Specific Metabolism: The Division of Labor 939 of fats, which serve as fuel throughout the body as well as thermal insulation; in the brain, cells pump ions across their plasma membranes to produce electrical signals. The liver plays a central processing and distributing role in metabolism and furnishes all other organs and tissues with an appropriate mix of nutrients via the bloodstream. The functional centrality of the liver is indicated by the common reference to all other tissues and organs as “extrahepatic.” We therefore begin our discussion of the division of metabolic labor by considering the transformations of carbohydrates, amino acids, and fats in the mammalian liver. This is followed by brief descriptions of the primary metabolic functions of adipose tissue, muscle, brain, and the medium that interconnects all others: the blood.

The Liver Processes and Distributes Nutrients During digestion in mammals,

the three main classes of nutrients (carbohydrates, proteins, and fats) undergo enzymatic hydrolysis into their simple constituents. This breakdown is necessary because the epithelial cells lining the intestinal lumen absorb only relatively small molecules. Many of the fatty acids and monoacylglycerols released by digestion of fats in the intestine are reassembled within these epithelial cells into triacylglycerols (TAGs). After being absorbed, most sugars and amino acids and some reconstituted TAGs pass from intestinal epithelial cells into blood capillaries and travel in the bloodstream to the liver; the remaining TAGs enter adipose tissue via the lymphatic system. The portal vein (Fig. 23-11) is a direct route from the digestive organs to the liver, and liver therefore has first access to ingested nutrients. The liver has two main cell types. Kupffer cells are phagocytes, important in immune function. Hepatocytes, of primary interest here, transform dietary nutrients into the fuels and precursors required by other tissues and export them via the blood. The kinds and amounts of nutrients supplied to the liver vary with several factors, including the diet and the time between meals. The demand of extrahepatic tissues for fuels and precursors varies among organs and with the level of activity and overall nutritional state of the individual. To meet these changing circumstances, the liver has remarkable metabolic flexibility. For example, when the diet is rich in protein, hepatocytes supply themselves with high levels of enzymes for amino acid catabolism and gluconeogenesis. Within hours after a shift to a highcarbohydrate diet, the levels of these enzymes begin to drop and the hepatocytes increase their synthesis of enzymes essential to carbohydrate metabolism and fat synthesis. Liver enzymes turn over (are synthesized and degraded) at 5 to 10 times the rate of enzyme turnover in other tissues, such as muscle. Extrahepatic tissues also can adjust their metabolism to prevailing conditions, but none is as adaptable as the liver, and none is so central to the organism's overall metabolism. What follows is

Specialized metabolic functions of mammalian tissues. a survey of the possible fates of sugars, amino acids, and lipids that enter the liver from the bloodstream. To help you recall the metabolic transformations discussed here, Table 23-2 shows the major pathways and processes and indicates by figure number where each pathway is presented in detail. Here, we provide summaries of the pathways, referring to the numbered pathways and reactions in Figures 23-12 to 23-14.

Sugars The glucose transporter of hepatocytes (GLUT2) allows rapid, passive diffusion of glucose so that the concentration of glucose in a hepatocyte is essentially the same as that in the blood. Glucose entering hepatocytes is phosphorylated by hexokinase IV (glucokinase) to yield glucose 6-phosphate. Glucokinase has a much higher K_m for glucose (10 mM) than do the hexokinase isozymes in other cells (p. 603) and, unlike these other isozymes, it is not inhibited by its product, glucose 6-phosphate. The presence of glucokinase allows hepatocytes to continue phosphorylating glucose when the glucose concentration rises well above levels that would overwhelm other hexokinases. The high K_m of glucokinase also ensures that the phosphorylation of glucose in Transports ions to maintain membrane potential; integrates inputs from body and surroundings; sends signals to other organs. Cardiac muscle “Uses ATP 4 P} generated = a aerobically Í to pump blood. Lymphatic system P Carries lipids from intestine to liver. Synthesizes, stores, and mobilizes triacylglycerols. (Brown adipose tissue carries out thermogenesis.) Uses ATP generated aerobically or anaerobically to do mechanical work. A Skeletal muscle hepatocytes is minimal when the glucose concentration is low, preventing the liver from consuming glucose as fuel via glycolysis. This spares glucose for other tissues. Fructose, galactose, and mannose, all absorbed from the small intestine, are also converted to glucose 6-phosphate by enzymatic pathways

examined in Chapter 14. Glucose 6-phosphate is at the crossroads of carbohydrate metabolism in the liver. It may take any of several major metabolic routes (Fig. 23-12), depending on the current metabolic needs of the organism. By the action of various allosterically regulated enzymes, and through hormonal regulation of enzyme synthesis and activity, the liver directs the flow of glucose into one or more of these pathways. © Glucose 6-phosphate is dephosphorylated by glucose 6-phosphatase to yield free glucose (see Fig. 15-30), which is exported to replenish blood glucose. Export is the predominant pathway when glucose 6-phosphate is in limited supply, because the blood glucose concentration must be kept sufficiently high (4 mm) to provide adequate energy for the brain and other tissues. @ Glucose 6-phosphate not immediately needed to form blood glucose is converted to

Liver glycogen Hepatocyte | Glucose 6-phosphate → Glycolysis

Here and in Figures 23-13 and 23-14, anabolic pathways are generally shown leading upward, catabolic pathways leading downward, and distribution to other organs horizontally. The numbered processes in each figure are described in the text. liver glycogen or has one of several other fates. Following glycolysis and the pyruvate dehydrogenase reaction, the acetyl-CoA so formed can be oxidized for ATP production by the citric acid cycle, with ensuing electron transfer and oxidative phosphorylation yielding ATP. (Normally, however, fatty acids are the preferred fuel for ATP production in hepatocytes.) Acetyl-CoA can also serve as the precursor of fatty acids, which are incorporated into TAGs and phospholipids, and of cholesterol. Much of the lipid synthesized in the liver is transported to other tissues by blood lipoproteins. Alternatively, glucose 6-phosphate can enter the pentose phosphate pathway, yielding both reducing power (NADPH), needed for the biosynthesis of fatty acids and cholesterol, and p-ribose 5-phosphate, a precursor for nucleotide biosynthesis. NADPH is also an essential cofactor in the detoxification and elimination of many drugs and other xenobiotics metabolized in the liver. Amino Acids Amino acids that enter the liver follow several important metabolic routes (Fig. 23-13). They are precursors for protein synthesis, a process discussed in Chapter 27. The liver constantly renews its own proteins, which have a relatively high turnover rate (average half-life of hours to days), and is also the site of

During the interval between meals, especially if prolonged, some muscle protein is degraded to amino acids. These amino acids donate their amino groups (by transamination) to pyruvate, the product of glycolysis, to yield alanine, which @ is transported to the liver and deaminated. Hepatocytes convert the resulting pyruvate to blood glucose (via gluconeogenesis @), and the ammonia to urea for excretion @. One benefit of this glucose-alanine cycle (see Fig.

18-9) is the smoothing out of fluctuations in blood glucose between meals. The amino acid deficit incurred in muscles is made up after the next meal by incoming dietary amino acids. Lipids The fatty acid components of lipids entering hepatocytes also have several different fates (Fig. 23-14). @ Some are converted to liver lipids. ® Under most circumstances, fatty acids are the primary oxidative fuel in the 21-33 to 21-37 21-17; 21-23 to 21-28 liver. Free fatty acids may be activated and oxidized to yield acetyl-CoA and NADH. © The acetyl-CoA is further oxidized via the citric acid cycle, and @ oxidations in the cycle drive the synthesis of ATP by oxidative phosphorylation. @ Excess acetyl-CoA, not required by the liver, is converted to acetoacetate and B-hydroxybutyrate; these ketone bodies circulate in the blood to other tissues to be used as fuel for the citric acid cycle. Ketone bodies, unlike fatty acids, can pass the blood-brain barrier, providing the brain with a source of acetyl-CoA for energyyielding oxidation. Ketone bodies can supply a significant fraction of the energy in some extrahepatic tissues—up to one-third in the heart and as much as 60% to 70% in the brain during prolonged fasting. @ Some of the acetylCoA derived from fatty acids (and from glucose) is used for the biosynthesis of cholesterol, which is required for membrane synthesis. Cholesterol is also the precursor of all steroid hormones and of the bile salts, which are essential for the digestion and absorption of lipids.

Metabolism of fatty acids in the liver. The other two metabolic fates of lipids involve specialized mechanisms for the transport of insoluble lipids in blood. @ Fatty acids are converted to the phospholipids and TAGs of plasma lipoproteins, which carry lipids to adipose tissue for storage. @ Some free fatty acids are bound to serum albumin and carried to the heart and skeletal muscles, which take up and oxidize free fatty acids as a major fuel. Serum albumin is the most abundant plasma protein; one molecule can carry up to 10 molecules of free fatty acid. The liver thus serves as the body's distribution center, exporting nutrients in the correct proportions to other organs, smoothing out fluctuations in metabolism caused by intermittent food intake, and processing excess amino groups into urea and other products to be disposed of by the kidneys. Certain nutrients are stored in the liver, including iron ions and vitamin A. The liver also detoxifies foreign organic compounds, such as drugs, food additives, preservatives, and other possibly harmful agents with no food value. Detoxification often involves the cytochrome P-450-dependent hydroxylation of relatively insoluble organic compounds, making them sufficiently soluble for further breakdown and excretion (see Box 21-1).

Adipose Tissues Store and Supply Fatty Acids There are two distinct types of adipose tissue, white and brown (Fig. 23-15), with quite distinct roles, and we focus first on the more abundant of the two. White adipose tissue (WAT) is amorphous and widely distributed in the body: under the skin, around the deep blood vessels, and in the abdominal cavity. The adipocytes of

23.2 Tissue-Specific Metabolism: The Division of Labor 943 (a) White adipocyte (c) (d) FIGURE 23-15 Adipocytes of white and brown adipose tissue. Schematic views of typical mouse adipocytes from (a) white adipose tissue (WAT) and (b) brown adipose tissue (BAT). White adipocytes are larger and contain a single huge lipid droplet, which squeezes the mitochondria and nucleus against the plasma membrane. In brown adipocytes, mitochondria are much more prominent, the nucleus is near the center of the cell, and multiple small fat droplets are present. Below are shown scanning electron micrographs of adipocytes in (c) WAT and (d) BAT. In fat tissues, capillaries and collagen fibers form a

supporting network around spherical adipocytes. WAT are large (diameter 30 to 70 μm), spherical cells, completely filled with a single large lipid (TAG) droplet that constitutes about 65% of the cell mass and squeezes the mitochondria and nucleus into a thin layer against the plasma membrane (Fig. 23—15a, c). In humans, WAT typically makes up about 15% of the mass of a healthy young adult. The adipocytes are metabolically very active, responding quickly to hormonal stimuli in a metabolic interplay with the liver, skeletal muscles, and heart. Like other cell types, adipocytes have an active glycolytic metabolism, oxidize pyruvate and fatty acids via the citric acid cycle, and carry out oxidative phosphorylation. During periods of high carbohydrate intake, adipose tissue can convert glucose (via pyruvate and acetyl-CoA) to fatty acids, convert the fatty acids to TAGs, and store the TAGs as large fat globules— although in humans, much of the fatty acid synthesis occurs in hepatocytes. Adipocytes store TAGs arriving from the liver (carried in the blood as VLDL; see Fig. 21-40) and from the intestinal tract (carried in chylomicrons), particularly after meals rich in fat. When the demand for fuel rises (between meals, for example), lipases in adipocytes hydrolyze stored TAGs to release free fatty acids, which can travel in the bloodstream to skeletal muscle and the heart. The release of

944 Hormonal Regulation and Integration of Mammalian

Metabolism fatty acids from adipocytes is greatly accelerated by epinephrine, which stimulates the cAMP-dependent phosphorylation of perilipin and thus gives lipases specific for tri-, di-, and monoglycerides access to TAGs in the lipid droplet (see Fig. 17-3). Hormone-sensitive lipase is also stimulated by phosphorylation, but this is not the main cause of increased lipolysis. Insulin counterbalances this effect of epinephrine, decreasing the activity of the lipase. The breakdown and synthesis of TAGs in adipose tissue constitute a substrate cycle; up to 70% of the fatty acids released by the three lipases are reesterified in adipocytes, re-forming TAGs. Recall from Chapter 15 that such substrate cycles allow fine regulation of the rate and direction of flow of intermediates through a bidirectional pathway. In adipose tissue, glycerol liberated by adipocyte lipases cannot be reused in the synthesis of TAGs, because adipocytes lack glycerol kinase. Instead, the glycerol phosphate required for TAG synthesis is made from pyruvate by glyceroneogenesis, involving the cytosolic PEP carboxykinase (see Fig. 21-22). In addition to its central function as a fuel depot, adipose tissue plays an important role as an endocrine organ, producing and releasing hormones that signal the state of energy reserves and coordinate metabolism of fats and carbohydrates throughout the body. We return to this function later in the chapter when we discuss the hormonal regulation of body mass.

Brown Adipose Tissue Is Thermogenic In small vertebrates and hibernating animals, a significant proportion of the adipose tissue is brown adipose tissue (BAT), distinguished from WAT by its smaller (diameter 20 to 40 μm), differently shaped (polygonal, not round) adipocytes (Fig. 23-15b, d). Like white adipocytes, brown adipocytes store TAGs, but in several smaller lipid droplets per cell rather than as a single central droplet. BAT cells have more mitochondria and a richer supply of capillaries and innervation than WAT cells, and it is the cytochromes of mitochondria and the hemoglobin in capillaries that give BAT its characteristic brown color. A unique feature of brown adipocytes is their strong expression of the gene UCP 1, which encodes thermogenin, the mitochondrial uncoupling protein (see Fig. 19-36). Thermogenin activity is responsible for one of the principal functions of BAT: thermogenesis. In brown adipocytes, fatty acids stored in lipid

droplets are released, enter mitochondria, and undergo complete conversion to CO₂ via β oxidation and the citric acid cycle. The reduced FADH₂ and NADH so generated pass their electrons through the respiratory chain to molecular oxygen. In WAT, protons pumped out of the mitochondria during electron transfer reenter the matrix through ATP synthase, with the energy of electron transfer conserved in ATP synthesis. In BAT, thermogenin provides an alternative route for protons to reenter the matrix that bypasses ATP synthase; the energy of the proton gradient is thus dissipated as heat, which can maintain the body (especially the nervous system and viscera) at its optimal temperature when the ambient temperature is relatively low. In the human fetus, differentiation of fibroblast preadipocytes into BAT begins at the twentieth week of gestation, and at the time of birth BAT represents 1% to 5% of total body mass. The brown fat deposits are located where the heat generated by thermogenesis can ensure that vital tissues—blood vessels to the head, major abdominal blood vessels, and the viscera, including the pancreas, adrenal glands, and kidneys—are not chilled as the newborn enters a world of lower ambient temperature (Fig. 23-16). At birth, WAT development begins and BAT begins to disappear. Young adult humans have much diminished deposits of BAT, from 3% of all adipose tissue in males to 7% in females, making up less than 0.1% of body mass. However, adults apparently have BAT that can be activated by cold exposure and suppressed by increasing the core body temperature (Fig. 23-16b). Adipocytes of BAT produce heat by oxidation of their own fatty acids, but they take up and oxidize both fatty acids and glucose from the blood at rates out of proportion to their mass. In fact, the detection of BAT by PET scanning depends on the adipocytes' relatively high rate of glucose uptake and metabolism (Fig. 23-16b). Humans with pheochromocytoma (tumors of the adrenal gland) overproduce epinephrine and norepinephrine, and one effect is differentiation of preadipocytes into discrete regions of BAT, localized roughly as in newborns. In the adaptation to warm or cold surroundings, and in the normal differentiation of WAT and BAT, the nuclear transcription factor PPAR γ (described later in the chapter) plays a central role. Muscles Use ATP for Mechanical Work Metabolism in the cells of skeletal muscle—myocytes—is specialized to generate ATP as the immediate source of energy for contraction. Moreover, skeletal muscle is adapted to do its mechanical work in an

intermittent fashion, on demand. Sometimes skeletal muscles must work at their maximum capacity for a short time, as in a 100 m sprint; at other times more prolonged work is required, as in running a marathon or in extended physical labor. There are two general classes of muscle tissue, which differ in physiological role and fuel utilization. Slow-twitch muscle, also called red muscle, provides relatively low tension but is highly resistant to fatigue. It produces ATP by the relatively slow but steady process of oxidative phosphorylation. Red muscle is very rich in mitochondria and is served by very dense networks of blood vessels, which bring the oxygen essential to ATP production. Fast-twitch muscle, or white muscle, has fewer mitochondria than red muscle and is less well supplied with blood vessels, but it can develop greater tension and do so faster. White muscle is quicker to fatigue because when active, it uses ATP faster than it can

23.2 Tissue-Specific Metabolism: The Division of Labor

945 «at (b) FIGURE 23-16 Brown adipose tissue in infants and adults. (a) At birth, human infants have brown fat distributed as shown here, to protect the spine, major blood vessels, and the internal organs. (b) PET scans of a 45-year-old woman injected with ^{18}F -deoxyglucose (to detect tissue that rapidly metabolizes glucose; see Fig. 23-23) reveal tumors of the left lung and lymph node, the right adrenal gland, and a lumbar vertebra (left). The replace it. There is a genetic component to the proportion of red and white muscle in any individual; with training, the endurance of fast-twitch muscle can be improved. Skeletal muscle can use free fatty acids, ketone bodies, or glucose as fuel, depending on the degree of muscular activity (Fig. 23-17). In resting muscle, the primary fuels are free fatty acids from adipose tissue and ketone bodies from the liver. These are oxidized and degraded to yield acetyl-CoA, which enters the citric acid cycle for oxidation to COs. The ensuing transfer of electrons to O provides the energy for ATP synthesis by oxidative phosphorylation. Moderately active muscle uses blood glucose in addition to fatty acids and ketone bodies. The glucose is phosphorylated, then degraded by glycolysis to pyruvate, which is converted to acetyl-CoA and oxidized via the citric acid cycle and oxidative phosphorylation. In maximally active fast-twitch muscles, the demand for ATP is so great that the blood flow cannot provide Os and fuels fast enough to supply sufficient ATP by $> v$. heart and bladder were also intensely labeled as expected, but in addition there was striking metabolic activity in the regions that normally have brown fat in infants. When the same patient was warmed for 48 hours before the PET scan (right), these typical brown fat areas were not active, indicating that this adult had brown fat deposits, which were metabolically active only when the core body temperature was relatively low. Different fuels are used for ATP synthesis during bursts of heavy activity and during light activity or rest. Phosphocreatine can rapidly supply ATP.

946 Hormonal Regulation and Integration of Mammalian Metabolism BOX 23-2 In animal tissues that have a high and fluctuating need for ATP, primarily skeletal muscle, cardiac muscle, and brain, there are several isozymes of creatine kinase. A cytosolic isozyme is present in regions of high ATP use (myofibrils and sarcoplasmic reticulum, for example). By converting ADP produced during periods of high ATP use back to ATP, this isozyme prevents the accumulation of ADP to concentrations that could inhibit ATP-using enzymes by mass action. Another isozyme of creatine kinase is located in regions where the inner and outer membranes of mitochondria come into contact. This mitochondrial isozyme (mCK) probably serves to shuttle ATP equivalents produced in the mitochondria to cytosolic sites of ATP use (Fig. 1). The species that diffuses from the mitochondrion to ATP-consuming activities in the cytosol is therefore creatine phosphate, not ATP. The mCK isozyme colocalizes with the adenine nucleotide transporter (in the inner mitochondrial membrane) and porin (in the outer mitochondrial membrane), suggesting that these three components may function together to transport ATP formed in the mitochondria into the cytosol. In knockout mice lacking the mitochondrial isozyme, myocytes compensate by producing more mitochondria, closely associated with myofibrils and sarcoplasmic reticulum, allowing quick diffusion of mitochondrial ATP to those sites of ATP use. Nevertheless, these mice have reduced capacity for running, indicating a defect in some aspect of energy-supplying metabolism. Creatine and phosphocreatine spontaneously break down to form creatinine (Fig. 2). To maintain high creatine levels, these losses have to be replaced, either by dietary creatine, obtained primarily from meats (muscle) and dairy products, or by the de novo synthesis of creatine from glycine, arginine, and methionine (Fig. 22-28), which occurs primarily in liver and kidney. De novo synthesis of creatine is a major consumer of these amino acids, particularly in aerobic respiration alone. Under these conditions, stored muscle glycogen is broken down to lactate by fermentation (p. 548). Each glucose unit degraded yields three ATP, because phosphorolysis of glycogen produces glucose 6-phosphate (via glucose 1-phosphate), sparing the ATP normally consumed in the hexokinase reaction. Lactic acid fermentation thus responds more quickly than oxidative phosphorylation to an increased need for

ATP, supplementing basal ATP production by aerobic oxidation of other fuels via the citric acid cycle and respiratory chain. The use of blood glucose and muscle glycogen as fuels for muscular activity.

Creatine and Creatine Kinase: Invaluable Diagnostic Aids and the Muscle Builder's Friends

Cytosolic ATP consumption is a 10^6 ATPases. Direction set by $[ATP]/[ADP]$ ratio. Cytosol Cr, PCr, ATP production by glycolysis, ATP production by oxidative phosphorylation.

FIGURE 1 Mitochondrial creatine kinase (mCK) transfers a phosphoryl group from ATP to creatine (Cr) to form creatine phosphate (PCr), which diffuses to sites of ATP use, where cytosolic creatine kinase (cCK) then passes the phosphoryl group back into ATP. Cytosolic CK can also use ATP produced by glycolysis to synthesize PCr. During periods of little ATP demand, the pools of ATP and PCr are replenished in preparation for the next period of intense demand for ATP. In resting muscle, the concentration of PCr is 3 to 5 times that of ATP, buffering the cell against rapid depletion of ATP during short bursts of ATP demand. It is greatly enhanced by the secretion of epinephrine, which stimulates both the release of glucose from liver glycogen and the breakdown of glycogen in muscle tissue. (Epinephrine mediates the so-called fight-or-flight response, discussed more fully below.) The relatively small amount of glycogen (about 1% of the total weight of skeletal muscle) limits the amount of glycolytic energy available during all-out exertion. Moreover, the accumulation of lactate and consequent decrease in pH in maximally active muscles reduces their efficiency. Skeletal muscle, however, contains another source of ATP, phosphocreatine (10 to 30 mM),

 must be replaced by biosynthesis or from the diet. vegans, for
 whom this is the only source of creatine; plants do not contain
 creatine. Muscle tissue has a specific system to take up creatine,
 exported by liver or kidney, from the blood into cells, against a
 substantial concentration gradient. Efficient uptake of dietary
 creatine requires continuous exercise; without exercise, creatine
 supplementation is of little value. Heart muscle contains a unique
 isozyme of creatine kinase (the MB isozyme), which is not normally
 found in the blood but appears there when released from heart
 muscle damaged by a heart attack. The blood level of MB begins to
 rise within 2 hours of the heart attack, typically peaks 12 to 36
 hours after the heart attack, and returns to normal levels in 3 to 5
 days. Measurement of the MB isozyme in blood therefore confirms
 the diagnosis of a heart attack and indicates approximately when it
 occurred. Body builders who are adding muscle mass have a greater
 need for creatine and commonly take creatine which can rapidly
 regenerate ATP from ADP by the creatine kinase reaction: o~O—

 tissue. supplements of up to 20 g per day for a few days, followed
 by lower maintenance doses. The combination of exercise and
 creatine supplementation increases muscle mass (Fig. 3) and
 improves performance in high-intensity, short-duration work.
 Children with inborn errors in the enzymes of creatine synthesis or
 uptake suffer severe intellectual disability and seizures. These
 individuals have much-reduced levels of brain creatine as measured
 by NMR (see Fig. 23-18). Creatine supplementation raises their
 brain creatine and creatine phosphate concentrations and brings
 about partial improvement of the symptoms. In the healthy kidney,
 creatinine from creatine breakdown is efficiently cleared from the

blood into the urine. When renal function is defective, creatinine levels in the blood rise above the normal range of 0.8 to 1.4 mg/dL. Elevated blood creatinine is associated with renal failure in diabetes and other conditions in which renal function is temporarily or permanently compromised. Renal clearance of creatinine varies slightly with age, race, and gender, so correcting the calculation for those factors yields a more sensitive measure of the extent of renal function, the glomerular filtration rate (GFR). During periods of active contraction and glycolysis, this reaction proceeds predominantly in the direction of ATP synthesis; during recovery from exertion, the same enzyme resynthesizes phosphocreatine from creatine and ATP. Given the relatively high levels of ATP and phosphocreatine in muscle, these compounds can be detected in intact muscle, in real time, by NMR spectroscopy (Fig. 23-18). Creatine serves to shuttle ATP equivalents from the mitochondrion to sites of ATP consumption and can be the limiting factor in the development of new muscle tissue (Box 23-2).

948 Hormonal Regulation and Integration of Mammalian

Metabolism Intensity of signal (concentration of the compound)

Chemical shift (parts per million) (identity of the compound)

FIGURE 23-18 Phosphocreatine buffers ATP concentration during exercise. A "stack plot" of magnetic resonance spectra (of ^3P) showing inorganic phosphate (P_i), phosphocreatine (PCr), and ATP (each of its three phosphates giving a signal). The series of plots represents the passage of time, from a period of rest to one of exercise, and then of recovery. Note that the ATP signal hardly changes during exercise, kept high by continued respiration and by the reservoir of phosphocreatine, which diminishes during exercise. During recovery, when ATP production by catabolism is greater than ATP utilization by the (now resting) muscle, the phosphocreatine reservoir is refilled. After a period of intense muscular activity, the individual continues breathing heavily for some time, using much of the extra O_2 for oxidative phosphorylation in the liver. The ATP produced is used for gluconeogenesis (in the liver) from lactate that has been carried in the blood from the muscles. The glucose thus formed returns to the muscles to replenish their glycogen, completing the Cori cycle (Fig. 23-19; see also Box 15-4). Muscle: ATP produced by glycolysis for rapid contraction. Lactate — J Glycogen ATP Blood Blood glucose lactate

FIGURE 23-19 Metabolic cooperation between skeletal muscle and the liver: the Cori cycle. Extremely active muscles use glycogen as their energy source, generating lactate via glycolysis. During recovery, some of this lactate is transported to the liver and converted to glucose via gluconeogenesis. This glucose is released to the blood and returned to the muscles to replenish their glycogen stores. The overall pathway (glucose — lactate — glucose) constitutes the Cori cycle. Actively contracting skeletal muscle generates heat as a byproduct of imperfect coupling of the chemical energy of ATP with the mechanical work of contraction. This heat production can be put to good use when ambient temperature is low: skeletal muscle carries out shivering thermogenesis, rapidly repeated muscle contraction that produces heat but little motion, helping to maintain the body at its preferred temperature of 37°C . Heart muscle differs from skeletal muscle in that it is continuously active in a regular rhythm of contraction and relaxation and it has a completely aerobic metabolism at all times. Mitochondria are much

more abundant in heart muscle than in skeletal muscle, making up almost half the volume of the cells (Fig. 23-20). The heart uses mainly free fatty acids, but also some glucose and ketone bodies taken up from the blood, as sources of energy; these fuels are oxidized via the citric acid cycle and oxidative phosphorylation to generate ATP. Like skeletal muscle, heart muscle does not store lipids or glycogen in large amounts. It does have small amounts of reserve energy in the form of phosphocreatine, enough for a few seconds of contraction. Because the heart is normally aerobic and obtains its energy from oxidative phosphorylation, the failure of O_2 to reach part of the heart muscle when the blood vessels are blocked by lipid deposits (atherosclerosis) or blood clots (coronary thrombosis) can cause that region of the heart muscle to die. This is what happens in myocardial infarction, more commonly known as a heart attack.

E The Brain Uses Energy for Transmission of Electrical Impulses The metabolism of the brain is remarkable in several respects. The neurons of the adult mammalian brain

Mitochondria Actin-myosin contractile apparatus

FIGURE 23-20 Electron micrograph of heart muscle. In the profuse mitochondria of heart tissue, pyruvate (from glucose), fatty acids, and ketone bodies are oxidized to drive ATP synthesis. This steady aerobic metabolism allows the human heart to pump blood at a rate of nearly 6 L/min, or about 350 L/h—or 200×10^6 L of blood over 70 years.

normally use only glucose as fuel (Fig. 23-21). (Astrocytes, the other major cell type in the brain, can oxidize fatty acids.) The brain has a very active respiratory metabolism (Fig. 23-22); it uses O_2 at a fairly constant rate, accounting for almost 20% of the total O_2 consumed by the body at rest. Because the brain contains very little glycogen, it is constantly dependent on incoming glucose in the blood. Should blood glucose fall significantly below a critical level for even a short time, severe and sometimes irreversible changes in brain function may result. Although the neurons of the brain cannot directly use free fatty acids or lipids from the blood as fuels, they can, when necessary, use 8-hydroxybutyrate (a ketone body), formed from fatty acids in the liver. The capacity of the brain to oxidize B-hydroxybutyrate via acetylCoA becomes important during prolonged fasting or starvation, after liver glycogen has been depleted, because it allows the brain to use body fat as an energy source. This spares muscle proteins—until they become the brain's ultimate source of glucose (via gluconeogenesis in the liver) during severe starvation. Neurons oxidize glucose by glycolysis and the citric acid cycle, and the flow of electrons from these oxidations through the respiratory chain provides almost all the ATP used by these cells. Energy is required to create and maintain an electrical potential across the neuronal plasma membrane. The membrane contains an electrogenic ATP-driven antiporter, the Na^+K^+ ATPase, which simultaneously pumps 2 K^+ ions into and 3 Na^+ ions out of the neuron (see Fig. 11-38). The resulting transmembrane potential changes transiently as an electrical signal (action potential) sweeps from one end of a neuron to the other (see Fig. 12-26).

FIGURE 23-22 Glucose metabolism in the brain. The technique of positron emission tomography (PET) scanning shows metabolic activity in specific regions of the brain. PET scans allow

visualization of isotopically labeled glucose in precisely localized regions of the brain of a living person, in real time. A positron-emitting glucose analog (2- ^{18}F -fluoro-2-deoxy-D-glucose) is injected into the bloodstream; a few seconds later, a PET scan shows how much of the glucose has been taken up by each region of the brain—a measure of metabolic activity. Shown here are PET scans of front-to-back cross sections of the brain at three levels, from the top (at the left) downward (to the right). The scans compare glucose metabolism when the experimental subject (a) is rested and (b) has been deprived of sleep for 48 hours.

tials are the chief mechanism of information transfer in the nervous system, so depletion of ATP in neurons would have disastrous effects on all activities coordinated by neuronal signaling. Blood Carries Oxygen, Metabolites, and Hormones Blood mediates the metabolic interactions among all tissues. It transports nutrients from the small intestine to the liver and from the liver and adipose tissue to other organs; it also transports waste products from the extrahepatic tissues to the liver for processing and to the kidneys for excretion. Oxygen moves in the bloodstream from the lungs to the tissues, and CO_2 , generated by tissue respiration returns via the bloodstream to the lungs for exhalation. Blood also carries hormonal signals from one tissue to another. In its role as signal carrier, the circulatory system resembles the nervous system: both regulate and integrate the activities of different organs. The average adult human has 5 to 6 L of blood. Almost half of this volume is occupied by three types of blood cells (Fig. 23-23): erythrocytes (red cells), filled with hemoglobin and specialized for carrying O_2 and CO_2 ; much smaller numbers of leukocytes

950 Hormonal Regulation and Integration of Mammalian Metabolism

Blood plasma Inorganic components (10%) NaCl, bicarbonate, phosphate, CaCl₂, MgCl₂, KCl, Na₂SO₄, FIGURE 23-23 The composition of blood (by weight). Whole blood can be separated into blood plasma and cells by centrifugation. About 10% of blood plasma is solutes, of which about 10% consists of inorganic salts, 20% small organic molecules, and 70% plasma proteins. The major dissolved components are listed. Blood contains many other substances, often in trace amounts. These include other metabolites, enzymes, hormones, vitamins, trace elements, and bile pigments. Measurements of the concentrations of components in blood plasma are important in the diagnosis and treatment of many diseases.

(white cells) of several types (including lymphocytes, also found in lymphatic tissue), which are central to the immune system to defend against infections; and platelets, which help to mediate blood clotting. The liquid portion is the blood plasma, which is 90% water and 10% solutes. Dissolved or suspended in the plasma is a large variety of proteins, lipoproteins, nutrients, metabolites, waste products, inorganic ions, and hormones. More than 70% of the plasma solids are plasma proteins, primarily immunoglobulins (circulating antibodies), serum albumin, apolipoproteins involved in the transport of lipids, transferrin (for iron transport), and blood-clotting proteins such as fibrinogen and prothrombin. The ions and low molecular weight solutes in blood plasma are not fixed components but are in constant flux between blood and various tissues. Dietary uptake of the inorganic ions that are the predominant electrolytes of blood and cytosol (Na⁺, K⁺, and Ca²⁺) is, in general, counterbalanced by their excretion in the urine. For many blood components, something near a dynamic steady state is achieved: the concentration of the component changes little, although a continuous flux occurs between the digestive tract, blood, and urine. The plasma levels of Na⁺, K⁺, and Ca²⁺ remain close to 140, 5, and 2.5 mM, respectively, with little change in response to dietary intake. Any significant departure from these values can result in serious illness or death. The kidneys play an especially important role in maintaining ion balance by selectively filtering waste products and excess ions out of the blood while preventing the loss of essential nutrients and ions. The human erythrocyte loses its nucleus and mitochondria during

differentiation. It therefore relies on glycolysis alone for its supply of ATP. The lactate produced by glycolysis returns to the liver, where gluconeogenesis converts it to glucose, to be stored as glycogen or recirculated to the peripheral tissues. The erythrocyte has constant access to glucose in the bloodstream. The concentration of glucose in plasma is subject to tight regulation. We have noted the constant requirement of the brain for glucose and the role of the liver in maintaining blood glucose in the normal range, 60 to 90 mg/100 mL of whole blood (~ 4.5 mM). (Because erythrocytes make up a significant fraction of blood volume, their removal by centrifugation leaves a supernatant fluid, the plasma, containing the "blood glucose" in a smaller volume. To convert blood glucose to plasma glucose concentration, multiply the blood glucose level by 1.14.) When blood glucose in a human drops to 40 mg/100 mL (the hypoglycemic condition), the person experiences discomfort and mental confusion (Fig. 23-24); further reductions lead to coma, convulsions, and, in extreme hypoglycemia, death. Maintaining the normal concentration of glucose in blood is therefore a very high priority of the organism, and a variety of regulatory mechanisms have evolved to achieve that end. Among the most important regulators of blood glucose are the hormones insulin, glucagon, and epinephrine, as discussed in the next section.

E SUMMARY 23.2 Tissue-Specific Metabolism: The Division of Labor > In mammals there is a division of metabolic labor among specialized tissues and organs. The liver is the central distributing and processing organ for nutrients. Sugars and amino acids produced in digestion cross the intestinal epithelium and enter the blood, which carries them to the liver. Some triacylglycerols derived from ingested lipids also make their way to the liver, where the constituent fatty acids are used in a variety of processes. > Glucose 6-phosphate is the key intermediate in carbohydrate metabolism. It may be polymerized into glycogen, dephosphorylated to blood glucose, or converted to fatty acids via acetyl-CoA. It may

Blood glucose levels of 40 mg/100 mL and below constitute severe hypoglycemia. undergo oxidation by glycolysis, the citric acid cycle, and respiratory chain to yield ATP, or enter the pentose phosphate pathway to yield pentoses and NADPH. > Amino acids are used to synthesize liver and plasma proteins, or their carbon skeletons are converted to glucose and glycogen by gluconeogenesis; the ammonia formed by deamination is converted to urea. > The liver converts fatty acids to triacylglycerols, phospholipids, or cholesterol and its esters for transport as plasma lipoproteins to adipose tissue for storage. Fatty acids can also be oxidized to yield ATP or to form ketone bodies, which are circulated to other tissues. > White adipose tissue stores large reserves of triacylglycerols and releases them into the blood in response to epinephrine or glucagon. Brown adipose tissue is specialized for thermogenesis, the result of fatty acid oxidation in uncoupled mitochondria. > Skeletal muscle is specialized to produce and use ATP for mechanical work. During low to moderate muscular activity, oxidation of fatty acids and glucose is the primary source of ATP. During strenuous muscular activity, glycogen is the ultimate fuel, supplying ATP through lactic acid fermentation. During recovery, the lactate is reconverted (through gluconeogenesis) to glycogen and glucose in the liver for use in replenishing muscle glycogen supplies.

23.3 Hormonal Regulation of Fuel Metabolism

951 Phosphocreatine is an immediate source of ATP during active contraction. > Heart muscle obtains nearly all its ATP from oxidative phosphorylation, with fatty acids as the primary fuel. > The neurons of the brain use only glucose and B-hydroxybutyrate as fuels, the latter being important during fasting or starvation. The brain uses most of its ATP for the active transport of Na^+ and K^+ to maintain the electrical potential across the neuronal membrane. > The blood transfers nutrients, waste products, and hormonal signals among tissues and organs. It is made up of cells (erythrocytes, leukocytes, and platelets) and electrolyte-rich water (plasma) containing many proteins.

23.3 Hormonal Regulation of Fuel Metabolism

The minute-by-minute

adjustments that keep the blood glucose level near 4.5 mM involve the combined actions of insulin, glucagon, epinephrine, and cortisol on metabolic processes in many body tissues but especially in liver, muscle, and adipose tissue. Insulin signals these tissues that blood glucose is higher than necessary; as a result, cells take up excess glucose from the blood and convert it to glycogen and triacylglycerols for storage. Glucagon signals that blood glucose is too low, and tissues respond by producing glucose through glycogen breakdown and (in the liver) gluconeogenesis and by oxidizing fats to reduce the use of glucose. Epinephrine is released into the blood to prepare the muscles, lungs, and heart for a burst of activity. Cortisol mediates the body's response to longer-term stresses. We discuss these hormonal regulations in the context of three normal metabolic states—well fed, fasted, and starving—and look at the metabolic consequences of diabetes mellitus, a disorder that results from derangements in the signaling pathways that control glucose metabolism. Insulin Counters High Blood Glucose Acting through plasma membrane receptors (see Figs 12-15, 12-16), insulin stimulates glucose uptake by muscle and adipose tissue (Table 23-3), where the glucose is converted to glucose 6-phosphate. In the liver, insulin also activates glycogen synthase and inactivates glycogen phosphorylase, so that much of the glucose 6-phosphate is channeled into glycogen. Insulin also stimulates the storage of excess fuel as fat in adipose tissue (Fig. 23-25). In the liver, insulin activates both the oxidation of glucose 6-phosphate to pyruvate via glycolysis and the oxidation of pyruvate to acetyl-CoA. The excess of acetyl-CoA not needed for energy production is used for fatty acid synthesis, and the fatty acids are exported from the liver as the TAGs

The NADPH necessary for lipid synthesis is obtained by oxidation of glucose in the pentose phosphate pathway. Excess amino acids are converted to pyruvate and acetyl-CoA, which are also used for lipid synthesis. Dietary fats move via the lymphatic system, as chylomicrons, from the intestine to the liver, muscle, and adipose tissues.

of plasma lipoproteins (VLDL; see Fig. 21-40) to adipose tissue. Insulin stimulates the synthesis of TAGs in adipocytes, from fatty acids released from the VLDL triacylglycerols. These fatty acids are ultimately derived from the excess glucose taken up from blood by the liver. In summary, the effect of insulin is to favor the conversion of excess blood glucose to two storage forms: glycogen (in the liver and muscle) and triacylglycerols (in adipose tissue). Besides acting directly on muscle and liver to change their metabolism of carbohydrates and fats, insulin can act in the brain to signal these tissues indirectly, as described later.

Pancreatic 3 Cells Secrete Insulin in Response to Changes in Blood Glucose When glucose enters the bloodstream from the intestine after a carbohydrate-rich meal, the resulting increase in blood glucose causes increased secretion of insulin (and decreased secretion of glucagon) by the pancreas. Insulin release is largely regulated by the level of glucose in the blood supplying the pancreas. The peptide hormones insulin, glucagon, and somatostatin are produced by clusters of specialized pancreatic cells, the islets of Langerhans.

Hormonal Regulation of Fuel Metabolism Pancreas Islet of Langerhans + ~6 cell (insulin) L a cell (glucagon) 6 cell (somatostatin)

FIGURE 23-26 The endocrine system of the pancreas. The pancreas contains both exocrine cells (see Fig. 18-3b), which secrete digestive enzymes in the form of zymogens, and clusters of endocrine cells, the islets of Langerhans. The islets contain a, B, and 6 cells (also known as A, B, and D cells, respectively), each cell type secreting a specific peptide hormone. The islets of Langerhans (Fig. 23-26). Each cell type of the islets produces a single hormone: a cells produce glucagon; B cells, insulin; and 6 cells, somatostatin. [Ca²⁺]_i rises because of the opening of K⁺ channels in the insulin-secreting cell membrane. In response to this membrane-depolarization granules release insulin. Triggered by high [ATP], voltage-gated Ca²⁺ channels open, allowing Ca²⁺ to flow into the cell. (Ca²⁺ is also released from the endoplasmic reticulum, in response to the initial elevation of [Ca²⁺] in the cytosol.) — Insulin secretion Cytosolic [Ca²⁺] is now high enough to trigger insulin release by exocytosis. The numbered processes are discussed in the text. Ca²⁺ channel

954 Hormonal Regulation and Integration of Mammalian Metabolism

B cells, where it is immediately converted to glucose 6-phosphate by hexokinase IV (glucokinase) and enters glycolysis. With the higher rate of glucose catabolism, $[ATP]$ increases, causing the closing of ATP-gated K^+ channels in the plasma membrane. © Reduced efflux of K^+ depolarizes the membrane. (Recall from Section 12.6 that exit of K^+ through an open K^+ channel hyperpolarizes the membrane; closing the K^+ channel therefore effectively depolarizes the membrane.) Membrane depolarization opens voltage-gated Ca^{2+} channels, and @ the resulting increase in cytosolic $[Ca^{2+}]$ triggers © the release of insulin by exocytosis. The brain integrates inputs on energy supply and demand, and signals from the parasympathetic and sympathetic nervous system also affect (stimulate and inhibit, respectively) insulin release. A simple feedback loop limits hormone release: insulin lowers blood glucose by stimulating glucose uptake by the tissues; the reduced blood glucose is detected by the β cell as a diminished flux through the hexokinase reaction; this slows or stops the release of insulin. This feedback regulation holds blood glucose concentration nearly constant despite large fluctuations in dietary intake. The activity of ATP-gated K^+ channels is central to the regulation of insulin secretion by B cells. The channels are octamers of four identical Kir6.2 subunits and four identical SUR1 subunits and are constructed along the same lines as the K^+ channels of bacteria and those of other eukaryotic cells (see Figs 11-47 and 11-48). The four Kir6.2 subunits form a cone around the K^+ channel and function as the selectivity filter and ATP-gating mechanism (Fig. 23-28). When $[ATP]$ rises (indicating increased

FIGURE 23-28 ATP-gated K^+ channels in B cells. (a) The ATP-gated channel, viewed in the plane of the membrane. The channel is formed by four identical Kir6.2 subunits, and outside those are four SUR1 (sulfonylurea receptor) subunits. The SUR1 subunits have binding sites for ADP and the drug diazoxide, which favor the open channel, and tolbutamide, a sulfonylurea drug that favors the closed channel. The Kir6.2 subunits constitute the actual channel, and they contain, on the cytosolic side, binding sites for ATP and phosphatidylinositol 4,5-bisphosphate (PIP), which favor the closed and the open channel, respectively. (b) The structure of the Kir6.2 portion of the channel, viewed in the plane of the membrane. For clarity, only two

transmembrane domains and two cytosolic domains are shown. Three K⁺ ions (green) are shown in the region of the selectivity filter. Mutation in certain amino acid residues (shown in red) leads to neonatal diabetes; mutation in others (shown in blue) leads to hyperinsulinism of infancy. This structure (coordinates courtesy of Frances Ashford and her colleagues at the University of Oxford) was obtained not directly by crystallography but by mapping the known Kir6.2 sequence onto the crystal structures of a bacterial Kir channel (KirBac1.1; PDB ID 1P7B) and the amino and carboxyl domains of another Kir protein, Kir3.1 (PDB ID 1U4E). We compare this structure with the gated K⁺ channel in Figure 11-48. blood glucose), the K⁺ channels close, depolarizing the plasma membrane and triggering insulin release as shown in Figure 23-27. The sulfonylurea drugs, oral medications used in the treatment of type 2 diabetes mellitus, bind to the SUR1 (sulfonylurea receptor) subunits of the K⁺ channels, closing the channels and stimulating insulin release. The first generation of these drugs (tolbutamide, for example) was developed in the 1950s. The second-generation drugs, including glyburide (Micronase), glipizide (Glucotrol), and glimepiride (Amaryl), are more potent and have fewer side effects. (The sulfonylurea moiety is screened light red in the following structures.) The sulfonylureas are sometime used in combination with injected insulin but often suffice alone for controlling type 2 diabetes. O Cl ra I L NHCH₃CH₃ Re, = " "OCH₃; Glyburide O yoy
 ~"NHCH₃CH₃, |. aN H₃C Glipizide Mutations in the ATP-gated K⁺
 channels of B cells are, fortunately, rare. Mutations in Kir6.2 that
 result in constantly open K⁺ channels (red residues in Fig. 23-28b)
 lead to neonatal diabetes mellitus, with severe hyperglycemia that
 requires insulin therapy. Other mutations in Kir6.2 or SUR1 (blue
 residues in Fig. 23-28b) produce permanently closed K⁺ channels
 and continuous release of insulin. If untreated, individuals with
 these mutations develop congenital hyperinsulinemia
 (hyperinsulinism of infancy); excessive insulin causes severe
 hypoglycemia (low blood glucose) leading to irreversible brain
 damage. One effective treatment is surgical removal of part of the
 pancreas to reduce insulin production. ~ Glucagon = oe Liver
 FIGURE 23-29 The fasting state: the glucogenic liver. After some
 hours without a meal, the liver becomes the principal source of
 glucose for the brain. Liver glycogen is broken down, and the
 glucose 1-phosphate produced is converted to glucose 6-phosphate,
 then to free glucose, which is released into the bloodstream. Amino
 acids from the degradation of proteins in liver and muscle, and
 glycerol from the breakdown of TAGs in adipose tissue, are used for
 gluconeogenesis. The liver uses fatty acids as its principal fuel, and
 excess acetyl-CoA is converted to ketone bodies for export to other
 tissues; the brain is especially dependent on this fuel when glucose
 is in short supply (see Fig. 23-21). (Blue arrows follow the path of
 glucose; orange arrows, the path of lipids; and purple arrows, the
 path of amino acids.) t Th ai 23.3 Hormonal Regulation of Fuel
 Metabolism 955 Glucagon Counters Low Blood Glucose Several
 hours after the intake of dietary carbohydrate, blood glucose levels
 fall slightly because of the ongoing oxidation of glucose by the
 brain and other tissues. Lowered blood glucose triggers secretion of
 glucagon and decreases insulin release (Fig. 23-29). Glucagon
 causes an increase in blood glucose concentration in several ways
 (Table 23-4). Like epinephrine, it stimulates the net breakdown of
 liver glycogen by activating glycogen phosphorylase and
 inactivating glycogen synthase; both effects are the result of
 phosphorylation of the regulated enzymes, triggered by cAMP.
 Glucagon inhibits glucose breakdown by glycolysis in the liver and
 stimulates glucose synthesis by gluconeogenesis. Both effects result
 from lowering the concentration of fructose 2,6-bisphosphate, an

allosteric inhibitor of the gluconeogenic enzyme fructose 1,6-bisphosphatase (FBPase-1) and an activator of the glycolytic enzyme phosphofructokinase-1. Recall that [fructose 2,6-bisphosphate] is ultimately controlled by a cAMP-dependent protein phosphorylation reaction (see Fig. 15-19) Glucagon also inhibits the glycolytic enzyme pyruvate kinase (by promoting its cAMP-dependent phosphorylation), thus blocking the conversion of phosphoenolpyruvate to pyruvate and preventing oxidation of pyruvate via the citric acid cycle. The resulting “ Pancreas Glucose 6-phosphate Glycerol Fatty acids Adipose tissue Muscle CO,

This effect is augmented by glucagon's stimulation of the synthesis of the gluconeogenic enzyme PEP carboxykinase. By stimulating glycogen breakdown, preventing glycolysis, and promoting gluconeogenesis in hepatocytes, glucagon enables the liver to export glucose, restoring blood glucose to its normal level. Although its primary target is the liver, glucagon (like epinephrine) also affects adipose tissue, activating TAG breakdown by causing cAMP-dependent phosphorylation of perilipin and hormone-sensitive lipase. The activated lipase liberates free fatty acids, which are exported to the liver and other tissues as fuel, sparing glucose for the brain. The net effect of glucagon is therefore to stimulate glucose synthesis and release by the liver and to mobilize fatty acids from adipose tissue, to be used instead of glucose by tissues other than the brain. All these effects of glucagon are mediated by cAMP-dependent protein phosphorylation. During Fasting and Starvation, Metabolism Shifts to Provide Fuel for the Brain The fuel reserves of a healthy adult human are of three types: glycogen stored in the liver and, in smaller quantities, in muscles; large quantities of triacylglycerols in adipose tissues; and tissue proteins, which can be degraded when necessary to provide fuel (Table 23-5). UFES Available Metabolic Fuels in a Normal-Weight, 70 kg Man and in an Obese, 140 kg Man at the Beginning of a Fast Caloric equivalent Estimated survival Type of fuel Weight (kg) (thousands of kcal (kJ)) (months)* Normal-weight, 70 kg man Triacylglycerols (adipose tissue) 15 140 (590) Proteins (mainly muscle) 6 24 (100) Glycogen (muscle, liver)

Two hours after a meal, the blood glucose level is diminished slightly, and tissues receive glucose released from liver glycogen. There is little or no synthesis of triacylglycerols. By four hours after a meal, blood glucose has fallen further, insulin secretion has slowed, and glucagon secretion has increased. These hormonal signals mobilize triacylglycerols from adipose tissue, which now become the primary fuel for muscle and liver. Figure 23-30 shows the responses to prolonged fasting. ® To provide glucose for the brain, the liver degrades certain proteins—those most expendable in an organism not ingesting food. Their nonessential amino acids are transaminated or deaminated (Chapter 18), and the resulting NH₃ is converted into urea and excreted (green arrows). Glucogenic amino acids from protein breakdown (purple arrows) provide substrates for gluconeogenesis, and gluconeogenesis in the liver becomes the main source of glucose for the brain (blue arrows). NH₃ from amino acid deamination is converted into urea and excreted (green arrows). Glucogenic amino acids from protein breakdown (purple arrows) provide substrates for gluconeogenesis, and gluconeogenesis in the liver becomes the main source of glucose for the brain (blue arrows). Hormonal Regulation of Fuel Metabolism 957 @ the extra amino groups are converted to urea, which is exported via the bloodstream to the kidneys and excreted in the urine. Also in the liver, and to some extent in the kidneys, the carbon skeletons of glucogenic amino acids are converted to pyruvate or intermediates of the citric acid cycle. © These intermediates (as well as the glycerol derived from TAGs in adipose tissue) provide the starting materials for gluconeogenesis in the liver, @ yielding glucose for export to the brain. @ Fatty acids released from adipose tissue are oxidized to acetyl-CoA in the liver, but as oxaloacetate is depleted by the use of citric acid cycle intermediates for gluconeogenesis, @ entry of coenzyme A is exported to the brain. Fatty acids from adipose tissue are imported into the liver and oxidized to acetyl-CoA (orange arrows), and acetyl-CoA is the starting material for ketone body formation in the liver and export to brain to serve as the principal energy source (red arrows). When the concentration of ketone bodies in the blood exceeds the ability of the kidneys to reabsorb ketones, these compounds begin to appear in the urine.

958 Hormonal Regulation and Integration of Mammalian Metabolism

acetyl-CoA into the cycle is inhibited and acetyl-CoA accumulates. @ This favors the formation of acetoacetyl-CoA and ketone bodies. After a few days of fasting, the levels of ketone bodies in the blood rise (Fig. 23-31) as they are exported from the liver to the heart, skeletal muscle, and brain, which use these fuels instead of glucose (Fig. 23-30, O). Acetyl-CoA is a critical regulator of the fate of pyruvate: it allosterically inhibits pyruvate dehydrogenase and stimulates pyruvate carboxylase. In these ways, acetylCoA prevents its own further production from pyruvate while stimulating the conversion of pyruvate to oxaloacetate, the first step in gluconeogenesis. Triacylglycerols stored in the adipose tissue of a normal-weight adult could provide enough fuel to maintain a basal rate of metabolism for about three months; a very obese adult has enough stored fuel to endure a fast of more than a year (Table 23-5). When fat reserves are gone, the degradation of essential proteins begins; this leads to loss of heart and liver function and, in prolonged starvation, to death. Stored fat can provide adequate energy (calories) during a fast or rigid diet, but vitamins and minerals must be provided, and sufficient dietary glucogenic amino acids are needed to replace those being used for gluconeogenesis. Rations for those on a weight-reduction diet are commonly fortified with vitamins, minerals, and amino acids or proteins.

B-Hydroxybutyrate N Plasma concentration (mm) Free fatty acids Acetoacetate (0) 10 20 30 40 Days of starvation

FIGURE 23-31 Plasma concentrations of fatty acids, glucose, and ketone bodies during six weeks of starvation. Despite the hormonal mechanisms for maintaining the level of glucose in blood, glucose begins to diminish within 2 days of fasting (blue). The level of ketone bodies, almost unmeasurable before the fast, rises dramatically after 2 to 4 days of fasting (red), with B-hydroxybutyrate as the major contributor. These water-soluble ketones, acetoacetate and B-hydroxybutyrate, supplement glucose as an energy source for the brain during a long fast. Acetone, a minor ketone body, is not metabolized but is eliminated in the breath. A much smaller rise in blood fatty acids (orange) also occurs, but this rise does not contribute to energy metabolism in the brain, as fatty acids do not cross the blood-brain barrier. Epinephrine Signals Impending Activity When an animal is confronted with a stressful situation that

requires increased activity—fighting or fleeing, in the extreme case—neuronal signals from the brain trigger the release of epinephrine and norepinephrine from the adrenal medulla. Both hormones dilate the respiratory passages to facilitate the uptake of O_2 , increase the rate and strength of the heartbeat, and raise the blood pressure, thereby promoting the flow of O_2 and fuels to the tissues (Table 23-6). This is the “fight or flight” response. Epinephrine acts primarily on muscle, adipose, and liver tissues. It activates glycogen phosphorylase and inactivates glycogen synthase by cAMP-dependent phosphorylation of the enzymes, thus stimulating the conversion of liver glycogen to blood glucose, the fuel for anaerobic muscular work. Epinephrine also promotes the anaerobic breakdown of muscle glycogen by lactic acid fermentation, stimulating glycolytic ATP formation. The stimulation of glycolysis is accomplished by raising the concentration of fructose 2,6-bisphosphate, a potent allosteric activator of the key glycolytic enzyme phosphofructokinase-1. Epinephrine also stimulates fat mobilization in adipose tissue, activating (by cAMP-dependent phosphorylation) hormone-sensitive lipase and moving aside the perilipin covering the lipid droplet surface (see Fig. 17-3). Finally, epinephrine stimulates glucagon secretion and inhibits insulin secretion, reinforcing its effect of mobilizing fuels and inhibiting fuel storage.

Cortisol Signals Stress, Including Low Blood Glucose A variety of stressors (anxiety, fear, pain, hemorrhage, infection, low blood glucose, starvation) stimulate release of the corticosteroid hormone cortisol from the adrenal cortex. Cortisol acts on muscle, liver, and adipose tissue to supply the organism with fuel to withstand the stress. Cortisol is a relatively slow-acting hormone that alters metabolism by changing the kinds and amounts of certain enzymes synthesized in its target cells rather than by regulating the activity of existing enzyme molecules. In adipose tissue, cortisol leads to an increase in the release of fatty acids from stored TAGs. The exported fatty acids serve as fuel for other tissues, and the glycerol is used for gluconeogenesis in the liver. Cortisol stimulates the breakdown of nonessential muscle proteins and the export of amino acids to the liver, where they serve as precursors for gluconeogenesis. In the liver, cortisol promotes gluconeogenesis by stimulating synthesis of the key enzyme PEP carboxykinase; glucagon has the same effect, whereas insulin has the opposite effect. Glucose produced in this way is stored in the liver as

glycogen or exported immediately to tissues that need glucose for fuel. The net effect of these metabolic changes is to restore blood glucose to its normal level and to increase glycogen stores, ready to support the fight-or-flight response commonly associated with stress. The effects of

23.3 Hormonal Regulation of Fuel Metabolism 959 UIFSA

Physiological and Metabolic Effects of Epinephrine: Preparation for Action Immediate effect Overall effect Physiological $\uparrow$ Heart rate } Blood pressure } Dilation of respiratory passages Metabolic $\uparrow$ Glycogen breakdown (muscle, liver) } Glycogen synthesis (muscle, liver) $\uparrow$ Gluconeogenesis (liver) $\uparrow$ Glycolysis (muscle) $\uparrow$ Fatty acid mobilization (adipose tissue) $\uparrow$ Glucagon secretion $\downarrow$ Insulin secretion cortisol therefore counterbalance those of insulin. During extended periods of stress, the continued release of cortisol loses its positive adaptive value and begins to cause damage to muscle and bone and to impair endocrine and immune function. Diabetes Mellitus Arises from Defects in Insulin Production or Action Diabetes mellitus is a relatively common disease: nearly 6% of the U.S. population shows some degree of abnormality in glucose metabolism that is indicative of diabetes or a tendency toward the condition. There are two major clinical classes of diabetes mellitus: type 1 diabetes, sometimes referred to as insulin-dependent diabetes mellitus (IDDM), and type 2 diabetes, or non—insulin-dependent diabetes mellitus (NIDDM), also called insulin-resistant diabetes. Type 1 diabetes begins early in life, and symptoms quickly become severe. This disease responds to insulin injection, because the metabolic defect stems from an autoimmune destruction of pancreatic B cells and a consequent inability to produce sufficient insulin. Type 1 diabetes requires both insulin therapy and careful, lifelong control of the balance between dietary intake and insulin dose. Characteristic symptoms of type 1 (and type 2) diabetes are excessive thirst and frequent urination (polyuria), leading to the intake of large volumes of water (polydipsia) (“diabetes mellitus” means “excessive excretion of sweet urine”). These symptoms are due to the excretion of large amounts of glucose in the urine, a condition known as glucosuria. Type 2 diabetes is slow to develop (typically in older, obese individuals), and the symptoms are milder and often go unrecognized at first. This is really a group of diseases in which the regulatory activity of insulin is Increase delivery of Os to tissues (muscle) Increase production of glucose for fuel Increases ATP production in muscle Increases availability of fatty acids as fuel Reinforce metabolic effects of epinephrine disordered: insulin is produced, but some feature of the insulin-response system is defective. Individuals with this disorder are insulin-resistant. The

connection between type 2 diabetes and obesity (discussed below) is an active and exciting area of research. Individuals with either type of diabetes are unable to take up glucose efficiently from the blood; recall that insulin triggers the movement of GLUT4 glucose transporters to the plasma membrane in muscle and adipose tissue (see Fig. 12-16). With glucose unavailable, fatty acids become the principal fuel, which leads to another characteristic metabolic change in diabetes: excessive but incomplete oxidation of fatty acids in the liver. The acetyl-CoA produced by β oxidation cannot be completely oxidized by the citric acid cycle, because the high $[NADH]/[NAD^+]$ ratio produced by β oxidation inhibits the cycle (recall that three steps of the cycle convert NAD^+ to $NADH$). Accumulation of acetyl-CoA leads to overproduction of the ketone bodies, acetoacetate and β -hydroxybutyrate, which cannot be used by extrahepatic tissues as fast as they are made in the liver. In addition to β -hydroxybutyrate and acetoacetate, the blood of individuals with diabetes also contains acetone, which results from the spontaneous decarboxylation of acetoacetate: $O=C(CH_3)C(=O)CH_3 + H_2O \longrightarrow CH_3C(=O)CH_3 + HCO_2^-$; Acetoacetate Acetone Acetone is volatile and is exhaled, and in uncontrolled diabetes the breath has a characteristic odor sometimes mistaken for ethanol. A diabetic individual who is experiencing mental confusion due to high blood glucose is occasionally misdiagnosed as intoxicated, an error that can be fatal. The overproduction of ketone bodies, called ketosis, results in greatly increased concentrations of ketone bodies in the blood (ketonemia) and urine (ketonuria).

960 Hormonal Regulation and Integration of Mammalian Metabolism The ketone bodies are carboxylic acids, which ionize, releasing protons. In uncontrolled diabetes this acid production can overwhelm the capacity of the blood's bicarbonate buffering system and produce a lowering of blood pH called acidosis or, in combination with ketosis, ketoacidosis, a potentially life-threatening condition. Biochemical measurements on blood and urine samples are essential in the diagnosis and treatment of diabetes. A sensitive diagnostic criterion is provided by the glucose-tolerance test. The individual fasts overnight, then drinks a test dose of 100 g of glucose dissolved in a glass of water. The blood glucose concentration is measured before the test dose and at 30 min intervals for several hours thereafter. A healthy individual assimilates the glucose readily, the blood glucose rising to no more than about 9 or 10 mmw; little or no glucose appears in the urine. In diabetes, individuals assimilate the test dose of glucose poorly; their blood glucose level rises dramatically and returns to the fasting level very slowly. Because the blood glucose levels exceed the kidney threshold (about 10 mm), glucose also appears in the urine.

E SUMMARY 23.3 Hormonal Regulation of Fuel Metabolism > The concentration of glucose in blood is hormonally regulated. Fluctuations in blood glucose (normally 60 to 90 mg/100 mL, or about 4.5 mm) due to dietary intake or vigorous exercise are counterbalanced by a variety of hormonally triggered changes in metabolism in several organs. > High blood glucose elicits the release of insulin, which speeds the uptake of glucose by tissues and favors the storage of fuels as glycogen and triacylglycerols while inhibiting fatty acid mobilization in adipose tissue. > Low blood glucose triggers release of glucagon, which stimulates glucose release from liver glycogen and shifts fuel metabolism in liver and muscle to fatty acid oxidation, sparing glucose for use by the brain. In prolonged fasting, triacylglycerols become the principal fuel; the liver converts the fatty acids to ketone bodies for export to other tissues, including the brain. > Epinephrine prepares the body for increased activity by mobilizing glucose from glycogen and other precursors, releasing it into the blood. > Cortisol, released in response to a variety of stressors (including low blood glucose), stimulates gluconeogenesis from amino acids and glycerol in the liver, thus raising blood glucose and counterbalancing the effects of

insulin. > In diabetes, insulin is either not produced or not recognized by the tissues, and the uptake of blood glucose is compromised. When blood glucose levels are high, glucose is excreted. Tissues then depend on fatty acids for fuel (producing ketone bodies) and degrade cellular proteins to provide glucogenic amino acids for glucose synthesis. Uncontrolled diabetes is characterized by high glucose levels in the blood and urine and the production and excretion of ketone bodies.

23.4 Obesity and the Regulation of Body Mass

In the U.S. population, 30% of adults are obese and another 35% are overweight, as defined in terms of body mass index (BMI), calculated as $(\text{weight in kg}) / (\text{height in m})^2$. A BMI below 25 is considered normal; an individual with a BMI of 25 to 30 is overweight; a BMI greater than 30 indicates obesity. Obesity is life-threatening. It significantly increases the chances of developing type 2 diabetes as well as heart attack, stroke, and cancers of the colon, breast, prostate, and endometrium.

Consequently, there is great interest in understanding how body mass and the storage of fats in adipose tissue are regulated. To a first approximation, obesity is the result of taking in more calories in the diet than are expended by the body's fuel-consuming activities. The body can deal with an excess of dietary calories in three ways: (1) convert excess fuel to fat and store it in adipose tissue, (2) burn excess fuel by extra exercise, and (3) "waste" fuel by diverting it to heat production (thermogenesis) by uncoupled mitochondria. In mammals, a complex set of hormonal and neuronal signals acts to keep fuel intake and energy expenditure in balance so as to hold the amount of adipose tissue at a suitable level. Dealing effectively with obesity requires understanding these various checks and balances under normal conditions and how these homeostatic mechanisms can fail.

Adipose Tissue Has Important Endocrine Functions

One early hypothesis to explain body-mass homeostasis, the "adiposity negative-feedback" model, postulated a mechanism that inhibits eating behavior and increases energy expenditure whenever body weight exceeds a certain value (the set point); the inhibition is relieved when body weight drops below the set point (Fig. 23-32). This model predicts that a feedback signal originating in adipose tissue influences the brain centers that control eating behavior and activity (metabolic and motor activity). The first such factor, leptin, was discovered in 1994, and subsequent research revealed that adipose tissue is an

important endocrine organ that produces peptide hormones, known as adipokines. Adipokines may act locally (autocrine and paracrine action) or systemically (endocrine action), carrying information about the adequacy of the energy reserves (TAGs) stored in adipose tissue to other tissues and to the brain. Normally, adipokines produce changes in fuel metabolism and feeding behavior that reestablish adequate fuel reserves and maintain body mass. When adipokines are over- or underproduced, the resulting dysregulation may result in life-threatening disease.

Food fat synthesis & $\downarrow$, | P 11 | Adipose Hu. Leptin tissue
 intake | Cue | $\downarrow$ | fat oxidation @ Gummas # j Energy, heat

FIGURE 23-32 Set-point model for maintaining constant mass. When the mass of adipose tissue increases (dashed outline), released leptin inhibits feeding and fat synthesis and stimulates oxidation of fatty acids. When the mass of adipose tissue decreases (solid outline), lowered leptin production favors greater food intake and less fatty acid oxidation. Leptin (Greek leptos, “thin”) is an adipokine (167 amino acids) that, on reaching the brain, acts on receptors in the hypothalamus to curtail appetite. Leptin was first identified as the product of a gene designated OB (obese) in laboratory mice. Mice with two defective copies of this gene (ob/ob genotype; lowercase letters signify a mutant form of the gene) show the behavior and physiology of animals in a constant state of starvation: their plasma cortisol levels are elevated; they are unable to stay warm, exhibit unrestrained appetite, grow abnormally, and do not reproduce. As a consequence of the unrestrained appetite, they become severely obese, weighing as much as three times more than normal mice (Fig. 23-33). They also have metabolic disturbances very similar to those seen in diabetes, and they are insulin-resistant. When leptin is injected into ob/ob mice, they eat less, lose weight, and increase their locomotor activity and thermogenesis. **FIGURE 23-33 Obesity caused by defective leptin production.** Both of these mice, which are the same age, have defects in the OB gene. The mouse on the right was injected daily with purified leptin and weighs 35 g. The mouse on the left got no leptin and consequently ate more food and was less active; it weighs 67 g.

23.4 Obesity and the Regulation of Body Mass 961 A second mouse gene, designated DB (diabetic), also has a role in appetite regulation. Mice with two defective copies (db/db) are obese and diabetic. The DB gene encodes the leptin receptor. When the receptor is defective, the signaling function of leptin is lost. The leptin receptor is expressed primarily in regions of the brain known to regulate feeding behavior—neurons of the arcuate nucleus of the hypothalamus (Fig. 23-34a). Leptin carries the message that fat reserves are sufficient, and it promotes a reduction in (a) Ventromedial Paraventricular nucleus nucleus ; Pá | wh Arcuate 7) _ Hypothalamus nucleus _ i?  their uncoupled oxidation in mitochondria, generating heat but not
 ATP.

962 Hormonal Regulation and Integration of Mammalian

Metabolism fuel intake and increased expenditure of energy.

Leptinreceptor interaction in the hypothalamus alters the release of neuronal signals to the region of the brain that affects appetite.

Leptin also stimulates the sympathetic nervous system, increasing blood pressure, heart rate, and thermogenesis by uncoupling the mitochondria of brown adipocytes (Fig. 23-34b). Recall that thermogenin, or UCP1, forms a channel in the inner mitochondrial membrane that allows protons to reenter the mitochondrial matrix without passing through the ATP synthase complex. This permits continual oxidation of fuel (fatty acids in a brown adipocyte) without ATP synthesis, dissipating energy as heat and consuming dietary calories or stored fats in potentially very large amounts.

Leptin Stimulates Production of Anorexigenic Peptide Hormones

Two types of neurons in the arcuate nucleus control fuel intake and metabolism (Fig. 23-35). The orexigenic (appetite-stimulating)

neurons stimulate eating by producing and releasing neuropeptide Y (NPY), which causes the next neuron in the circuit to send the signal to the brain: Eat! The blood level of NPY rises during

starvation and is elevated in both ob/ob and db/db mice. The high NPY concentration presumably contributes to the obesity of these mice, who eat voraciously. Effectors Muscle V > Adipose \$ 4_s

Leptin Insulin PYY3.36 GLP-1 Ghrelin (adipose) (pancreas) (gut)

(stomach) Adiposity Satiety Hunger signals signals signal The anorexigenic (appetite-suppressing) neurons in the arcuate nucleus produce α -melanocyte—stimulating hormone (α -MSH; also known as melanocortin), formed from its polypeptide precursor pro-opiomelanocortin (POMC; Fig. 23-5). Release of α -MSH causes the next neuron in the circuit to send the signal to the brain: Stop eating! The amount of leptin released by adipose tissue depends on both the number and the size of adipocytes. When weight loss decreases the mass of lipid tissue, leptin levels in the blood decrease, the production of NPY increases, and the processes in adipose tissue shown in Figure 23-34 are reversed. Uncoupling is diminished, slowing thermogenesis and saving fuel, and fat

mobilization slows in response to reduced signaling by cAMP. Consumption of more food combined with more efficient utilization of fuel results in replenishment of the fat reserve in adipose tissue, bringing the system back into balance. Leptin may also be essential to the normal development of hypothalamic neuronal circuits. In mice, the outgrowth of nerve fibers from the arcuate nucleus during early brain development is slower in the absence of leptin, affecting both the orexigenic and (to a lesser extent) anorexigenic outputs of the hypothalamus. It is possible that the leptin levels during development of these circuits determine the details of the hardwiring of this regulatory system.

Leptin Triggers a Signaling Cascade That Regulates Gene Expression

The leptin signal is transduced by a mechanism also used by receptors for interferon and growth factors, the JAK/STAT system (Fig. 23-36; see Fig. 12-18). The leptin receptor, which has a single transmembrane segment, dimerizes when leptin binds to the extracellular domains of two monomers. Both monomers are phosphorylated on a Tyr residue of their intracellular domain by a Janus kinase (JAK). The phosphorylated Tyr residues become docking sites for other proteins.

FIGURE 23-35 Hormones that control eating. In the arcuate nucleus of the hypothalamus, two sets of neurosecretory cells receive hormonal input and relay neuronal signals to the cells of muscle, adipose tissue, and liver. Leptin and insulin are released from adipose tissue and pancreas, respectively, in proportion to the mass of body fat. The two hormones act on anorexigenic neurosecretory cells to trigger release of α -MSH (melanocyte-stimulating hormone); α -MSH carries the signal to second-order neurons in the hypothalamus, which puts out the signals to eat less and metabolize more fuel. Leptin and insulin also act on orexigenic neurosecretory cells to inhibit the release of NPY, reducing the “eat more” signal sent to the tissues. As described later in the text, the gastric hormone ghrelin stimulates appetite by activating the NPY-expressing cells; PYY₃₋₃₆, released from the colon, inhibits these neurons and thereby decreases appetite. Each of the two types of neurosecretory cells inhibits hormone production by the other, so any stimulus that activates orexigenic cells inactivates anorexigenic cells, and vice versa. This strengthens the effect of stimulatory inputs.

Leptin receptor Plasma membrane monomer || |G —
Cytosol A T = a, = Nucleus Neuropeptide (POMC, etc.)

FIGURE 23-36 The JAK-STAT mechanism of leptin signal transduction in the hypothalamus. Leptin binding induces dimerization of the leptin receptor, followed by phosphorylation of specific Tyr residues in the receptor's cytosolic domain, catalyzed by Janus kinase (JAK). STATs bound to the phosphorylated leptin receptor are now phosphorylated on Tyr residues by a separate activity of JAK. The STATs dimerize, binding each other's p-Tyr residues, and enter the nucleus. Here, they bind specific regulatory regions in the DNA and alter the expression of certain genes. The products of these genes ultimately influence the organism's feeding behavior and energy expenditure.

sites for three proteins that are signal transducers and activators of transcription (STATs 3, 5, and 6; sometimes called fat-STATs). The docked STATs are then phosphorylated on Tyr residues by the same JAK. After phosphorylation, the STATs dimerize, then move to the nucleus, where they bind to specific DNA sequences and stimulate the expression of target genes, including the gene for POMC, from which α -MSH is produced. The increased catabolism and thermogenesis triggered by leptin are due in part to increased synthesis of the mitochondrial uncoupling protein thermogenin (product of the UCP1 gene) in brown adipocytes. Leptin stimulates the synthesis of thermogenin by altering synaptic transmissions from neurons in the arcuate nucleus to adipose and other tissues via the sympathetic nervous system. The resulting increased release of norepinephrine in these tissues acts through α -adrenergic receptors to stimulate transcription of the UCP1 gene. The resulting uncoupling of electron transfer from oxidative phosphorylation consumes fat and is thermogenic (Fig. 23-34).

Might human obesity be the result of insufficient leptin production, and therefore treatable by the injection of leptin? Blood levels of leptin are in fact usually much higher in obese animals (including humans) than 23.4 Obesity and the Regulation of Body Mass 963 in animals of normal body mass (except, of course, in ob/ob mutants, which cannot make leptin). Some downstream element in the leptin response system must be defective in obese individuals, and the elevation in leptin is the result of an (unsuccessful) attempt to overcome the leptin resistance. In those very rare humans with extreme obesity who have a defective leptin gene (OB), leptin injection does result in

dramatic weight loss. In the vast majority of obese individuals, however, the OB gene is intact. In clinical trials, the injection of leptin did not have the weight-reducing effect observed in obese ob/ob mice. Clearly, most cases of human obesity involve one or more factors in addition to leptin.

The Leptin System May Have Evolved to Regulate the Starvation Response

The leptin system probably evolved to adjust an animal's activity and metabolism during periods of fasting and starvation, not as a means to restrict weight gain. The reduction in leptin level triggered by nutritional deficiency reverses the thermogenic processes illustrated in Figure 23-34, allowing fuel conservation. In the hypothalamus, decreased leptin signal also triggers decreased production of thyroid hormone (slowing basal metabolism), decreased production of sex hormones (preventing reproduction), and increased production of glucocorticoids (mobilizing the body's fuel-generating resources). By minimizing energy expenditure and maximizing the use of endogenous reserves of energy, these leptin-mediated responses may allow an animal to survive periods of severe nutritional deprivation.

Insulin Acts in the Arcuate Nucleus to Regulate Eating and Energy Conservation

Insulin secretion may reflect both the size of fat reserves (adiposity) and the current energy balance (blood glucose level). In addition to its endocrine actions on various tissues, insulin acts in the central nervous system (in the hypothalamus) to inhibit eating (Fig. 23-35). Insulin receptors in the orexigenic neurons of the arcuate nucleus inhibit the release of NPY, and insulin receptors in the anorexigenic neurons stimulate α -MSH production, thereby decreasing fuel intake and increasing thermogenesis. By mechanisms discussed in Section 23.3, insulin also signals muscle, liver, and adipose tissues to increase the conversion of glucose to acetylCoA, providing the starting material for fat synthesis. The actions of leptin and insulin are not wholly independent. Leptin makes the cells of liver and muscle more sensitive to insulin. One hypothesis to explain this effect suggests cross talk between the protein tyrosine kinases activated by leptin and those activated by insulin.

Metabolism Insulin receptor Leptin — receptor Insulin \ ù Y | Plasma membrane Z Gi DS Cytosol v Inhibition of food intake

FIGURE 23-37 A possible mechanism for cross talk between receptors for insulin and leptin. The insulin receptor has intrinsic Tyr kinase activity (see Fig. 12-15), and the leptin receptor, when occupied by its ligand, is phosphorylated by a soluble Tyr kinase (JAK). One possible explanation for the observed interaction between leptin and insulin is that both may phosphorylate the same substrate—in the case shown here, insulin receptor substrate-2 (IRS-2). When phosphorylated, IRS-2 activates PI3K, which has downstream consequences that include inhibition of food intake. IRS-2 serves here as an integrator of the input from two receptors. (Fig. 23-37); common second messengers in the two signaling pathways allow leptin to trigger some of the same downstream events that are triggered by insulin, through insulin receptor substrate-2 (IRS-2) and phosphatidylinositol 3-kinase (PI3K) (see Fig. 12-16). Adiponectin Acts through AMPK to Increase Insulin Sensitivity Adiponectin is a peptide hormone (224 amino acids) produced almost exclusively in adipose tissue, an adipokine that sensitizes other organs to the effects of insulin, protects against atherosclerosis, and inhibits inflammatory responses (monocyte adhesion, macrophage transformation, and the proliferation and migration of the cells of vascular smooth muscle). Adiponectin circulates in the blood and powerfully affects the metabolism of fatty acids and carbohydrates in liver and muscle. It increases the uptake of fatty acids from the blood by myocytes and the rate at which fatty acids undergo β oxidation in muscle. It also blocks fatty acid synthesis and gluconeogenesis in hepatocytes, and stimulates glucose uptake and catabolism in muscle and liver. These effects of adiponectin are indirect and not fully understood, but AMPK clearly mediates many of them. Acting through its plasma membrane receptor, adiponectin triggers phosphorylation and activation of AMPK. Recall that AMPK is activated by factors that signal the need to shift metabolism away from biosynthesis and toward energy generation (Fig. 23-38). When activated, AMPK phosphorylates target proteins critical to the metabolism of lipids and carbohydrates, with profound effects on the metabolism of the whole animal (Fig. 23-39). Adiponectin receptors are also present in

the brain; the hormone activates AMPK in the hypothalamus, stimulating food intake and reducing energy expenditure. One enzyme regulated by AMPK in the liver and in white adipose tissue is acetyl-CoA carboxylase, which produces malonyl-CoA, the first intermediate committed to fatty acid synthesis. Malonyl-CoA is a powerful inhibitor of the enzyme carnitine acyltransferase I, which starts the process of β oxidation by transporting fatty acids into the mitochondrion (see Fig. 17-6). By phosphorylating and inactivating acetyl-CoA carboxylase, AMPK inhibits fatty acid synthesis while relieving the inhibition (by malonylCoA) of β oxidation (see Fig. 17-13). Cholesterol synthesis is also inhibited by AMPK, which phosphorylates and inactivates HMG-CoA reductase, an enzyme in the path to cholesterol (see Fig. 21-34). Similarly, AMPK inhibits fatty acid synthase and acyl transferase, effectively blocking the synthesis of triacylglycerols. In short, lipid synthesis is inhibited and lipid use as fuel is stimulated. Mice with defective adiponectin genes are less sensitive to insulin than those with normal adiponectin, and they show poor glucose tolerance: ingestion of dietary carbohydrate causes a long-lasting rise in blood glucose. These metabolic defects resemble those of humans with type 2 diabetes, who are similarly insulin-insensitive and clear glucose from the blood only slowly. Indeed, individuals with obesity or type 2 diabetes have lower blood adiponectin levels than nondiabetic controls. Moreover, drugs used in the treatment of type 2 diabetes—the thiazolidinediones, such as rosiglitazone (Avandia) and pioglitazone (Actos) (p. 852)—increase the expression of adiponectin mRNA.

Extended fasting or starvation results in decreased reserves of triacylglycerols in adipose tissue, which triggers adiponectin production and release from adipocytes. The rise in plasma adiponectin acts through its plasma membrane receptors in various cell types and organs to inhibit energy-consuming processes and stimulate energyproducing processes. Adiponectin acts through its receptors in the brain to stimulate feeding behavior and inhibit energy-consuming physical activity, and to inhibit thermogenesis in brown fat. Adiponectin exerts its metabolic effects by activating AMPK, which regulates (by phosphorylation) specific enzymes in key metabolic processes (see in adipose tissue and increase blood adiponectin levels in experimental animals; they also activate AMPK (Fig. 23-39). (In 2011 the FDA concluded that Avandia use was associated with an increased risk of heart attacks, and it therefore limited the use of the drug to those diabetes patients for whom other available treatments were ineffective.) It seems likely that adiponectin will prove to be an important link between type 2 diabetes and its most important predisposing factor, obesity. E mTORC1 Activity Coordinates Cell Growth with the Supply of Nutrients and Energy The activity of a second novel protein kinase helps to mediate cell proliferation and increased cell size in response to growth factors and energy and nutrient availability. The highly conserved Ser/Thr kinase mTORC1 is activated by abundant energy and nutrient supplies (such as high concentrations of branchedchain amino acids). When activated, mTORC1 phosFig. 15-8). PFK-2,

phosphofructokinase-2; GLUT1 and GLUT4, glucose transporters; FAS, fatty acid synthase; ACC, acetyl-CoA carboxylase; HSL, hormone-sensitive lipase; HMGCR, HMG-CoA reductase; GPAT, an acyl transferase; GS, glycogen synthase; eEF2, eukaryotic elongation factor 2 (required for protein synthesis; see Chapter 27); mTOR1, mammalian target of rapamycin (a protein kinase that regulates protein availability; see Fig. 23-40). Thiazolidinedione drugs activate the transcription factor PPAR γ (see Fig. 23-41 and 23-42), which then turns on adiponectin synthesis, indirectly activating AMPK. Exercise, through conversion of ATP to ADP and AMP, also stimulates AMPK. Exercise phosphorylates several transcription factors, leading to increased expression of genes encoding the enzymes of lipid synthesis and mitochondrial proliferation and increased ribosome biogenesis (Fig. 23-40). Fasting results in inactivation of mTORC1, leading to increased breakdown of protein and glycogen in liver and muscle and mobilization of triglycerides in adipose tissue. Chronic activation of mTORC1 by overeating results in excess deposition of triglycerides in adipose tissue and also in liver and muscle. This abnormal lipid accumulation in liver and muscle may contribute to insulin insensitivity and type 2 diabetes, as described in Section 23.5. Mutations that produce constantly activated mTORC1 are also commonly associated with human cancers.

Diet Regulates the Expression of Genes Central to Maintaining Body Mass

Proteins in a family of ligand-activated transcription factors, the peroxisome proliferator-activated receptors (PPARs), respond to changes in dietary lipid by

966 Hormonal Regulation and Integration of Mammalian Metabolism

Nutrients Growth factors Pentoses cate Cell growth and proliferation | altering the expression of genes involved in fat and carbohydrate metabolism. These transcription factors were first recognized for their roles in peroxisome synthesis—thus their name. Their normal ligands are fatty acids or fatty acid derivatives, but they can also bind synthetic agonists and can be activated in the laboratory by genetic manipulation. PPAR α , PPAR δ , and PPAR γ are members of this nuclear receptor superfamily. They act in the nucleus by forming heterodimers with another nuclear receptor, RXR (retinoid X receptor), binding to regulatory regions of DNA near the genes under their control and changing the rate of transcription of those genes (Fig. 23-41). Ligand Plasma U membrane > | PPAR Cytosol Ligand γ | / RXR Nuclear envelope | Regulated gene f Response element (DNA sequence that regulates transcription in response to PPAR ligand L) FIGURE 23-41 Mode of action of PPARs. PPARs are transcription factors that, when bound to their cognate ligand (L), form heterodimers with the nuclear receptor RXR. The dimer binds specific regions of DNA known as response elements, stimulating transcription of genes in those regions.

Mitochondrial metabolism FIGURE 23-40 mTORC1 stimulates cell growth and proliferation when adequate nutrition is available. mTORC1 is a Ser/ Thr protein kinase activated by growth factors and metabolites that signal a state of adequate nutrition. By phosphorylating key target proteins, mTORC1 activates energy (ATP and NADPH) production for biosynthesis and stimulates the synthesis of proteins and lipids, allowing cell growth and proliferation. (PPP is pentose phosphate pathway; FA is fatty acids.)

PPAR γ is activated by the thiazolidinedione drugs that are used to treat type 2 diabetes (discussed below). PPAR α is expressed in liver, kidney, heart, skeletal muscle, and brown adipose tissue. The ligands that

activate this transcription factor include eicosanoids, free fatty acids, and the class of drugs called fibrates, such as fenofibrate (TriCor) and ciprofibrate (Modalin), which are used to treat coronary heart disease by raising HDL and lowering blood triacylglycerols. In hepatocytes, PPAR α turns on the genes necessary for the uptake and β oxidation of fatty acids and formation of ketone bodies during fasting. PPAR δ and PPAR γ are key regulators of fat oxidation, which act by sensing changes in dietary lipid. PPAR δ acts in liver and muscle, stimulating the transcription of at least nine genes encoding proteins for β oxidation and for energy dissipation through uncoupling of mitochondria. Normal mice overfed on high-fat diets accumulate massive amounts of white fat, and fat droplets accumulate in the liver. But when the same overfeeding experiment is carried out with mice that have a genetically altered, always active PPAR δ , this fat accumulation is prevented. In mice with a nonfunctioning leptin receptor (db/db), activated PPAR δ prevents the development of obesity that would otherwise occur. By stimulating fatty acid breakdown in uncoupled mitochondria, PPAR δ causes fat depletion, weight loss, and thermogenesis. Seen in this light, thermogenesis is both a means of keeping warm and a defense against obesity. Clearly, PPAR δ is a potential target for drugs to treat obesity.

Short-Term Eating Behavior Is Influenced by Ghrelin and PYY3_3, Ghrelin is a peptide hormone (28 amino acids) produced in cells lining the stomach. It was originally recognized as the stimulus for the release of growth hormone (ghre is the Proto-Indo-European root of “grow”), then subsequently shown to be a powerful appetite stimulant

Fat synthesis Fat synthesis Fatty acid oxidation and storage

 PPAR γ Insulin Fatty acid oxidation H. sensitivity Muscle that works
 on a shorter time scale (between meals) than leptin and insulin.
 Ghrelin receptors are located in the pituitary gland (presumably
 mediating growth hormone release) and in the hypothalamus
 (affecting appetite), as well as in heart muscle and adipose tissue.
 Ghrelin acts through a G protein-coupled receptor to generate the
 second messenger IP₃, which mediates ghrelin action. The
 concentration of ghrelin in the blood varies strikingly between
 meals, peaking just before a meal and dropping sharply just after
 the meal (Fig. 23-43). Injection of ghrelin into humans produces
 immediate sensations of intense hunger. Individuals with Prader-
 Willi syndrome, whose blood levels of ghrelin are exceptionally
 high, have an uncontrollable appetite, leading to extreme obesity
 that often results in death before the age of 30. PYY₃₋₃₆ is a
 peptide hormone (2 amino-terminal Y residues plus 34 amino acids)
 secreted by endocrine cells in the lining of the small intestine and
 colon in response to food entering from the stomach. The level of
 PYY₃₋₃₆ in the blood rises after a meal and remains high for some
 hours. It is carried in the blood to the arcuate nucleus, where it acts
 on orexigenic neurons, inhibiting NPY release and reducing hunger
 (Fig. 23-35). Humans injected with PYYs-ss feel little hunger and
 eat less than normal amounts for about 12 hours.

968 Hormonal Regulation and Integration of Mammalian Metabolism

Microbial Symbionts in the Gut Influence Energy Metabolism and Adipogenesis

Lean and obese individuals harbor different combinations of microbial symbionts in the gut. Investigation of this observation led to the discovery that certain microorganisms of the gut release fermentation products, namely the short-chain fatty acids acetate, propionate, butyrate, and lactate, which enter the bloodstream and trigger metabolic changes in adipose tissue. Propionate, for example, drives the expansion of WAT by acting on G protein-coupled receptors (GPR43 and GPR41) in the plasma membranes of several cell types, including adipocytes. These receptors trigger differentiation of precursor cells into adipocytes and inhibit lipolysis in existing adipocytes, leading to an increase in WAT mass—obesity. These findings suggest possible approaches to the prevention of obesity that involve altering the makeup of the microbial community in the gut, either by direct addition of microbial species (probiotics) that disfavor adipogenesis or by adding to the diet nutrients (prebiotics) that favor the dominance of the probiotic microbes. For example, certain polymers of fructose (fructans) that are indigestible to animals favor such a microbial community in mice and lead to decreased fat storage in WAT and liver (and to the decrease in insulin sensitivity associated with obesity and lipid deposition in the liver; see below). Endocrine cells present in the lining of the GI tract secrete products—the anorexigenic peptides PYY₃₋₃₅ and glucagon-like peptide-1 (GLP-1) and the orexigenic peptide ghrelin—that modulate food intake and energy expenditure in the animal. Interaction with specific microbes in the gut, or with their fermentation products, may be the trigger for release of these peptides. The investigations of effects of diet on microbial symbionts of the gut, and of the effects of microbial products on energy metabolism and adipogenesis, may lead to a deeper understanding of the effects of diet and microbial symbionts on the development of obesity and of its pathological sequels, the metabolic syndrome and type 2 diabetes. This interlocking system of neuroendocrine controls of food intake and metabolism presumably evolved to protect against starvation and to eliminate counterproductive accumulation of fat (extreme obesity). The difficulty most people face in trying to lose weight testifies to the remarkable effectiveness of these controls.

SUMMARY 23.4 Obesity and the Regulation of Body Mass >

Obesity is increasingly common in the United States and other developed countries and predisposes people toward several life-threatening conditions, including cardiovascular disease and type 2 diabetes. > Adipose tissue produces leptin, a hormone that regulates feeding behavior and energy expenditure so as to maintain adequate reserves of fat. Leptin production and release increase with the number and size of adipocytes. > Leptin acts on receptors in the arcuate nucleus of the hypothalamus, causing the release of anorexigenic (appetite-suppressing) peptides, including α -MSH, that act in the brain to inhibit eating. Leptin also stimulates sympathetic nervous system action on adipocytes, leading to uncoupling of mitochondrial oxidative phosphorylation, with consequent thermogenesis. > The signal-transduction mechanism for leptin involves phosphorylation of the JAK-STAT system. On phosphorylation by JAK, STATs can bind to regulatory regions in nuclear DNA and alter the expression of genes for proteins that set the level of metabolic activity and determine feeding behavior. Insulin acts on receptors in the arcuate nucleus, with results similar to those caused by leptin. > The hormone adiponectin stimulates fatty acid uptake and oxidation and inhibits fatty acid synthesis. It also sensitizes muscle and liver to insulin. Adiponectin's actions are mediated by AMPK, which is also activated by low [AMP] and exercise. > Ghrelin, a hormone produced in the stomach, acts on orexigenic (appetite-stimulating) neurons in the arcuate nucleus to produce hunger before a meal. PYY3 36, a peptide hormone of the intestine, acts at the same site to lessen hunger after a meal. > The specific types of microbial symbionts in the gut can influence adipogenesis, the increase in the mass of body fat.

23.5 Obesity, the Metabolic Syndrome, and Type 2 Diabetes

In the industrialized world, where the food supply is more than adequate, there is a growing epidemic of obesity and the type 2 diabetes associated with it. As many as 300 million people in the world now have diabetes, and reasonable projections predict a dramatic rise in cases over the next decade, following the world epidemic of obesity. The pathology of diabetes includes cardiovascular disease, renal failure, blindness, poor healing in the extremities that requires amputations, and neuropathy. In 2011, the global mortality from diabetes was estimated at 4 million, a number that is sure to rise in coming years. Clearly, it is essential to understand type 2 diabetes and its

relationship to obesity and to find countermeasures that prevent or reverse the damage done by this disease. E In Type 2 Diabetes the Tissues Become Insensitive to Insulin The hallmark of type 2 diabetes is the development of insulin resistance: a state in which more insulin is needed to bring about the biological effects

produced by a lower amount of insulin in the normal, healthy state. In the early stages of the disease, pancreatic B cells secrete enough insulin to overcome the lower insulin sensitivity of muscle and liver. But the B cells eventually fail, and the lack of insulin becomes apparent in the body's inability to regulate blood glucose. The intermediate stage, preceding type 2 diabetes mellitus, is sometimes called the metabolic syndrome, or syndrome X. This is typified by obesity, especially in the abdomen; hypertension (high blood pressure); abnormal blood lipids (high TAG and LDL, low HDL); slightly high blood glucose; and a reduced ability to clear glucose in the glucose-tolerance test. Individuals with metabolic syndrome often also show changes in blood proteins, changes that are associated with abnormal clotting (high fibrinogen concentration) or inflammation (high concentrations of the C-reactive peptide, which typically increases with an inflammatory response). About 27% of the adult population in the United States has these symptoms of metabolic syndrome. What predisposes individuals with metabolic syndrome to develop type 2 diabetes? According to the "lipid toxicity" hypothesis (Fig. 23-44), the action of PPAR γ on adipocytes normally keeps the cells ready to catabolize TAG. In lean individuals, TAG is catabolized. In overweight individuals, TAG is stored in adipocytes. Overloading adipocytes with triacylglycerols triggers inflammation in fat tissue and ectopic lipid deposition and insulin resistance in muscle. In an individual of healthy body mass, triacylglycerol (TAG) uptake in the diet equals TAG oxidation for energy. In overweight individuals, excess caloric intake results in enlarged adipocytes, engorged with TAG and unable to store more. Enlarged adipocytes secrete MCP-1 (monocyte chemoattractant protein-1), attracting macrophages. Macrophages infiltrate adipose tissue and produce TNF α (tumor necrosis factor α), which triggers lipid breakdown and fatty acid release into the blood. The fatty acids released from adipose tissue enter muscle cells, where they accumulate in small lipid droplets. This ectopic storage of lipids somehow triggers a pro-inflammatory state. Enlarged adipocytes produce macrophage chemoattractant protein (MCP-1).

23.5 Obesity, the Metabolic Syndrome, and Type 2 Diabetes 969

synthesize and store triacylglycerols—the adipocytes are insulin-

sensitive and produce leptin, which leads to their continued intracellular deposition of TAG. However, excess caloric intake in obese individuals causes adipocytes to become filled with TAG, leaving adipose tissue unable to meet any further demand for TAG storage. Lipid-filled adipose tissue releases protein factors that attract macrophages, which infiltrate the tissue and may come to represent as much as 50% of the adipose tissue by mass. Macrophages trigger the inflammatory response, which impairs TAG deposition in adipocytes and favors release of free fatty acids into the blood. These excess fatty acids enter liver and muscle cells, where they are converted to TAGs that accumulate as lipid droplets. This ectopic (Greek *ektopos*, “out of place”) deposition of TAGs leads to insulin insensitivity in liver and muscle, the hallmark of type 2 diabetes. Moreover, according to this hypothesis, excess stored fatty acids and TAGs are toxic to liver and muscle. Some individuals are less well equipped genetically to handle this burden of ectopic lipids and are more susceptible to the cellular damage that leads to the development of type 2 diabetes. Insulin resistance probably involves impairment of several of the mechanisms by which Chronic inflammation Macrophages infiltrate adipose tissue in response to MCP-1. O Macrophages in adipose tissue produce TNF α , which favors export of fatty acids. Adipocytes export fatty acids to muscle, where ectopic lipid deposits form. (7) Ectopic lipid interferes with GLUT4 movement to the myocyte surface, producing insulin resistance. Glucose Insulin-resistant muscle with reduced glucose transport causes insulin resistance, perhaps by triggering lipid-activated protein kinases that inactivate some element in the insulin-signaling pathway. GLUT4 glucose transporters leave the muscle cell surface, preventing glucose entry into muscle; the myocyte has now become insulin-resistant. It cannot use blood glucose for its fuel, so fatty acids are mobilized from adipose tissue and become the primary fuel. The increased influx of fatty acids into muscle leads to further deposition of ectopic lipids. In some individuals, insulin resistance develops into type 2 diabetes. Other individuals are genetically less susceptible to the deleterious effects of ectopic lipid storage or are genetically better equipped to manage this storage and do not develop diabetes.

970 Hormonal Regulation and Integration of Mammalian Metabolism

insulin acts on metabolism, which include changes in protein levels and changes in the activities of signaling enzymes and transcription factors. For example, both adiponectin synthesis in adipocytes and adiponectin level in the blood decrease with obesity and increase with weight loss. Several of the drugs that are effective in improving insulin sensitivity in type 2 diabetes are known to act on specific proteins in signaling pathways, and their actions are consistent with the lipotoxicity model. Thiazolidinediones bind to PPAR γ , turning on a set of adipocytespecific genes and promoting the differentiation of preadipocytes to small adipocytes, thereby increasing the body's capacity for absorbing fatty acids from the diet and storing them as TAGs. There are clearly genetic factors that predispose toward type 2 diabetes. Although 80% of individuals with type 2 diabetes are obese, most obese individuals do not develop type 2 diabetes. Given the complexity of the regulatory mechanisms we have discussed in this chapter, it is not surprising that the genetics of diabetes is complex, involving interactions between variant genes and environmental factors, including diet and lifestyle. At least 10 genetic loci have been reliably linked to type 2 diabetes; variation in any of these "diabetogenes" alone would cause a relatively small increase in the likelihood of developing type 2 diabetes. For example, people with a variant PPAR γ in which an Ala residue replaces Pro at position 12 are at a slightly, though significantly, increased risk of developing type 2 diabetes. E

Type 2 Diabetes Is Managed with Diet, Exercise, and Medication

Studies show that three factors improve the health of individuals with type 2 diabetes: dietary restriction, regular exercise, and drugs that increase insulin sensitivity or insulin production. Dietary restriction (and accompanying weight loss) reduces the overall burden of handling fatty acids. The lipid composition of the diet influences, through PPARs and other transcription factors, the expression of genes that encode proteins involved in fatty acid oxidation and in energy expenditure via thermogenesis. Exercise activates AMPK, as does adiponectin; AMPK shifts metabolism toward fat oxidation and inhibits fat synthesis. Several classes of drugs are used in the management of type 2 diabetes, some of which we have discussed earlier in the chapter (Table 23-7). Sulfonylureas act on the ATP-gated K*

channels in β cells to stimulate insulin release. Biguanides such as metformin (Glucophage) activate AMPK, mimicking the effects of adiponectin. Thiazolidinediones act through PPAR γ to increase the concentration of adiponectin in plasma and to stimulate adipocyte differentiation, thereby increasing the capacity for TAG storage. Inhibitors of dipeptide protease IV (DPP IV) prevent the proteolytic degradation of GLP-1, a peptide hormone produced in the gut that stimulates pancreatic insulin secretion. Inhibition of the peptidase prolongs the action of GLP-1, effectively increasing insulin secretion.

| TABLE 23-7 | F Treatments for Type 2 Diabetes Mellitus

Intervention/treatment	Weight loss	Direct target	content	Exercise
[AMP]/[ATP]	Sulfonylureas: glipizide (Glucotrol), glyburide (several brands), glimepiride (Amaryl)	blocked	Biguanides: metformin (Glucophage)	Thiazoladinediones: troglitazone (Rezulin),* rosiglitazone (Avandia)," pioglitazone (Actos)
PPAR γ	GLP-1 modulators: exenatide (Byetta), sitagliptin (Januvia)			

*Voluntarily withdrawn because of side effects. Adipose tissue; reduces TAG AMPK, activated by increasing Pancreatic B cells; K⁺ channels AMPK, activated Glucagon-like peptide-1, dipeptide protease IV Effect of treatment Reduces lipid burden; increases capacity for lipid storage in adipose tissue; restores insulin sensitivity Aids weight loss; see Fig. 23-39 Stimulates insulin secretion by pancreas; see Fig. 23-27 Increases glucose uptake by muscle; decreases glucose production in liver Stimulates expression of genes, potentiating the action of insulin in liver, muscle, adipose tissue; increases glucose uptake; decreases glucose synthesis in liver Enhances insulin secretion by pancreas 'Prescriptions limited to patients not helped by other treatment, because of possible increased risk of cardiovascular disease.

The combination of weight loss and exercise is the preferred way to prevent development of the metabolic syndrome and type 2 diabetes. Recent findings concerning BAT in adults suggest an interesting possibility for aiding weight loss and reducing the amount of TAG that must be stored. The protein PRDM16 is expressed strongly, and perhaps uniquely, in brown adipose tissue. When overexpressed in the adipose tissue of mice, PRDM16 induces the differentiation of preadipocytes in white adipose tissue into brown adipocytes, with high levels of thermogenin and strikingly uncoupled respiration. Such cells could, in principle, consume fatty acids above the amount needed for ATP production, converting the energy of oxidation to heat. Given the widespread and increasing occurrence of type 2 diabetes, the possibility of stimulating fat oxidation by activating BAT certainly deserves exploration.

E SUMMARY 23.5 Obesity, the Metabolic Syndrome, and Type 2 Diabetes

- > The metabolic syndrome, which includes obesity, hypertension, elevated blood lipids, and insulin resistance, is often the prelude to type 2 diabetes.
- > The insulin resistance that characterizes type 2 diabetes may be a consequence of abnormal lipid storage in muscle and liver, in response to a lipid intake that cannot be accommodated by adipose tissue.
- > Expression of the enzymes of lipid synthesis is under tight and complex regulation. PPARs are transcription factors that determine the rate of synthesis of many enzymes involved in lipid metabolism and adipocyte differentiation.
- > Effective treatments for type 2 diabetes include exercise, appropriate diet, and drugs that increase insulin sensitivity or insulin production.

Problems

1. Peptide Hormone Activity Explain how two peptide hormones as structurally similar as oxytocin and vasopressin can have such different effects (see Fig. 23-9).
2. ATP and Phosphocreatine as Sources of Energy for Muscle During muscle contraction, the concentration of phosphocreatine in skeletal muscle drops while the concentration of ATP remains fairly constant. However, in a classic experiment, Robert Davies found that if he first treated muscle with 1-fluoro-2,4-dinitrobenzene (p. 98), the concentration of ATP declined rapidly while the concentration of phosphocreatine remained unchanged during a series of contractions. Suggest an explanation.
3. Metabolism of Glutamate in the Brain Brain tissue takes up glutamate from the blood, transforms it into glutamine, and releases the glutamine into the blood. What is accomplished by this metabolic conversion? How does it take place? The amount of glutamine produced in the brain can actually exceed the amount of glutamate entering from the blood. How does this extra glutamine arise? (Hint: You may want to review amino acid catabolism in Chapter 18; recall that NH_2 is very toxic to the brain.)
4. Proteins as Fuel during Fasting When muscle proteins are catabolized in skeletal muscle during a fast, what are the fates of the amino acids?
5. Absence of Glycerol Kinase in Adipose Tissue Glycerol 3-phosphate is required for the biosynthesis

of triacylglycerols. Adipocytes, specialized for the synthesis and degradation of triacylglycerols, cannot use glycerol directly because they lack glycerol kinase, which catalyzes the reaction $\text{Glycerol} + \text{ATP} \longrightarrow \text{glycerol 3-phosphate} + \text{ADP}$. How does adipose tissue obtain the glycerol 3-phosphate necessary for triacylglycerol synthesis?

Problems 973

6. Oxygen Consumption during Exercise A sedentary adult consumes about 0.05 L of O_2 in 10 seconds. A sprinter, running a 100 m race, consumes about 1 L of O_2 in 10 seconds. After finishing the race, the sprinter continues to breathe at an elevated (but declining) rate for some minutes, consuming an extra 4 L of O_2 , above the amount consumed by the sedentary individual. (a) Why does the need for O_2 increase dramatically during the sprint? (b) Why does the demand for O_2 remain high after the sprint is completed?

7. Thiamine Deficiency and Brain Function Individuals with thiamine deficiency show some characteristic neurological signs and symptoms, including loss of reflexes, anxiety, and mental confusion. Why might thiamine deficiency be manifested by changes in brain function?

8. Potency of Hormones Under normal conditions, the human adrenal medulla secretes epinephrine ($\text{C}_9\text{H}_{17}\text{NO}_3$) at a rate sufficient to maintain a concentration of 10^{-7} M in circulating blood. To appreciate what that concentration means, calculate the diameter of a round swimming pool, with a water depth of 2.0 m, that would be needed to dissolve 1.0 g (about 1 teaspoon) of epinephrine to a concentration equal to that in blood.

9. Regulation of Hormone Levels in the Blood The half-life of most hormones in the blood is relatively short. For example, when radioactively labeled insulin is injected into an animal, half of the labeled hormone disappears from the blood within 30 min. (a) What is the importance of the relatively rapid inactivation of circulating hormones? (b) In view of this rapid inactivation, how is the level of circulating hormone kept constant under normal conditions? (c) In what ways can the organism make rapid changes in the level of a circulating hormone?

10. Water-Soluble versus Lipid-Soluble Hormones On the basis of their physical properties, hormones fall into one of two categories: those that are very soluble in water but relatively insoluble in lipids (e.g., epinephrine) and those that are relatively insoluble in water but highly soluble in lipids (e.g., steroid hormones). In their role as regulators of cellular activity, most water-soluble hormones do not enter their target cells. The lipidsoluble hormones, by contrast, do

enter their target cells and ultimately act in the nucleus. What is the correlation between solubility, the location of receptors, and the mode of action of these two classes of hormones? 11. Metabolic Differences between Muscle and Liver in a “Fight-or-Flight”

Situation When an animal confronts a “fight-or-flight” situation, the release of epinephrine promotes glycogen breakdown in the liver, heart, and skeletal muscle. The end product of glycogen breakdown in the liver is glucose; the end product in skeletal muscle is pyruvate. (a) What is the reason for the different products of glycogen breakdown in the two tissues? (b) What is the advantage to an animal that must fight or flee of these specific glycogen breakdown routes?

974 Hormonal Regulation and Integration of Mammalian Metabolism 12. Excessive Amounts of Insulin Secretion:

Hyperinsulinism Certain malignant tumors of the pancreas cause excessive production of insulin by the β cells. Affected individuals exhibit shaking and trembling, weakness and fatigue, sweating, and hunger. (a) What is the effect of hyperinsulinism on the metabolism of carbohydrates, amino acids, and lipids by the liver? (b) What are the causes of the observed symptoms? Suggest why this condition, if prolonged, leads to brain damage.

13. **Thermogenesis Caused by Thyroid Hormones** Thyroid hormones are intimately involved in regulating the basal metabolic rate. Liver tissue of animals given excess thyroxine shows an increased rate of O_2 consumption and increased heat output (thermogenesis), but the ATP concentration in the tissue is normal. Different explanations have been offered for the thermogenic effect of thyroxine. One is that excess thyroxine causes uncoupling of oxidative phosphorylation in mitochondria.

How could such an effect account for the observations? Another explanation suggests that the thermogenesis is due to an increased rate of ATP utilization by the thyroxine-stimulated tissue. Is this a reasonable explanation? Why?

14. **Function of Prohormones** What are the possible advantages of synthesizing hormones as

prohormones?

15. **Sources of Glucose during Starvation** The typical human adult uses about 160 g of glucose per day, 120 g of which is used by the brain. The available reserve of glucose (~ 20 g of circulating glucose and ~ 190 g of glycogen) is adequate for about one day. After the reserve has been depleted during starvation, how would the body obtain more glucose?

16. **Parabiotic ob/ob Mice** By careful surgery, researchers can connect the circulatory systems of two mice so that the same blood circulates through both animals. In these parabiotic mice, products released into the blood by one animal reach the other animal via the shared circulation. Both animals are free to eat independently. If a mutant ob/ob mouse (both copies of the OB gene are defective) and a normal OB/OB mouse (two good copies of the OB gene) were made parabiotic, what would happen to the weight of each mouse?

17. **Calculation of Body Mass Index** A portly biochemistry professor weighs 260 lb (118 kg) and is 5 feet 8 inches (173 cm) tall. What is his body mass index? How much weight would he have to lose to bring his body mass index down to 25 (normal)?

18. **Insulin Secretion** Predict the

effects on insulin secretion by pancreatic B cells of exposure to the potassium ionophore valinomycin (Fig. 11-44). Explain your prediction.

19. Effects of a Deleted Insulin Receptor A strain of mice specifically lacking the insulin receptor of liver is found to have mild fasting hyperglycemia (blood glucose = 132 mg/dL, vs. 101 mg/dL in controls) and a more striking hyperglycemia in the fed state (glucose = 363 mg/dL, vs. 135 mg/dL in controls). The mice have higher than normal levels of glucose 6-phosphatase in the liver and elevated levels of insulin in the blood. Explain these observations.

20. Decisions on Drug Safety The drug Avandia (rosiglitazone) is effective in lowering blood glucose in patients with type 2 diabetes but also carries an increased risk of heart attack. If it were your responsibility to decide whether this drug should remain on the market (labeled with suitable warnings of its side effects) or should be withdrawn, what factors would you weigh in making your decision?

21. Type 2 Diabetes Medication The drugs acarbose (Precose) and miglitol (Glyset), used in the treatment of type 2 diabetes mellitus, inhibit α -glucosidases in the brush border of the small intestine. These enzymes degrade oligosaccharides derived from glycogen or starch to monosaccharides. Suggest a possible mechanism for the salutary effect of these drugs for individuals with diabetes. What side effects, if any, would you expect from these drugs. Why? (Hint: Review lactose intolerance, pp. 561-562).

Data Analysis Problem

22. Cloning the Pancreatic B-Cell Sulfonylurea Receptor Glyburide, a member of the sulfonylurea family of drugs shown on p. 955, is used to treat type 2 diabetes. It binds to and closes the ATP-gated K^+ channel shown in Figures 23-27 and 23-28. (a) Given the mechanism shown in Figure 23-27, would treatment with glyburide result in increased or decreased insulin secretion by pancreatic B cells? Explain your reasoning. (b) How does treatment with glyburide help reduce the symptoms of type 2 diabetes? (c) Would you expect glyburide to be useful for treating type 1 diabetes? Why or why not? Aguilar-Bryan and coauthors (1995) cloned the gene for the sulfonylurea receptor (SUR) portion of the ATP-gated K^+ channel from hamsters. The research team went to great lengths to ensure that the gene they cloned was in fact the SUR-encoding gene. Here we explore how it is possible for researchers to demonstrate that they have actually cloned the gene of interest rather than another gene. The first step was to obtain pure SUR protein. As was already known, drugs such

as glyburide bind SUR with very high affinity ($K_a < 10 \text{ nM}$), and SUR has a molecular weight of 140 to 170 kDa. Aguilar-Bryan and coworkers made use of the high-affinity glyburide binding to tag the SUR protein with a radioactive label that would serve as a marker to purify the protein from a cell extract. First, they made a radiolabeled derivative of glyburide, using radioactive iodine $\sim 1 \text{ MBq}$ of 5-Iodo-2-hydroxyglyburide (d) In preliminary studies, the ^{125}I -labeled glyburide derivative (hereafter, [^{125}I]glyburide) was shown to have the same K_d and binding characteristics as unaltered glyburide. Why was it necessary to demonstrate this (what alternative possibilities did it rule out)? Even though [^{125}I]glyburide bound to SUR with high affinity, a significant amount of the labeled drug would probably be degraded

dissociate from the SUR protein during purification. To prevent this, [¹²⁵I]glyburide had to be covalently cross-linked to SUR. There are many methods for covalent cross-linking; Aguilar-Bryan and coworkers used UV light. When aromatic molecules are exposed to short-wave UV, they enter an excited state and readily form covalent bonds with nearby molecules. By cross-linking the radiolabeled glyburide to the SUR protein, the researchers could simply track the I radioactivity to follow SUR through the purification procedure. Aguilar-Bryan and colleagues treated hamster HIT cells (which express SUR) with [¹²⁵I]glyburide and UV light, purified the I-labeled 140 kDa protein, and sequenced its amino-terminal 25 amino acid segment; they found the sequence PLAFCGTENHSAAYRVDQGVLNNGC. The investigators then generated antibodies that bound to two short peptides in this sequence, one that bound to PLAFCGTE and the other to HSAAYRVDQGYV, and showed that these antibodies bound the purified [¹²⁵I]-labeled 140 kDa protein. (e) Why was it necessary to include this antibody-binding step? Next, the researchers designed PCR primers based on the sequences above and cloned a gene from a hamster cDNA library that encoded a protein that included these sequences (see Chapter 9 on biotechnology methods). The cloned putative SUR cDNA hybridized to an mRNA of the appropriate length that was present in cells known to contain SUR. The putative SUR cDNA did not hybridize to any mRNA fraction of the mRNAs isolated from hepatocytes, which do not express SUR. (f) Why was it necessary to include this putative SUR cDNA-mRNA hybridization step? Data Analysis Problem 975 Finally, the cloned gene was inserted into and expressed in COS cells, which do not normally express the SUR gene. The investigators mixed these cells with [¹²⁵I]glyburide with or without a large excess of unlabeled glyburide, exposed the cells to UV light, and measured the radioactivity of the 140 kDa protein produced. Their results are shown in the table.

Added	Added excess I label	Cell	putative SUR	unlabeled	140 kDa
Experiment	type	cDNA?	glyburide?	protein	1
HIT	No	No	2	HIT	No
Yes	= 3	COS	No	No	4
COS	Yes	No	5	COS	Yes
Yes	=	(g)	Why	was no	"I-labeled 140 kDa protein found in experiment 2?
(h)	How	would you use the information in the table to argue that the cDNA encoded SUR?	(i)	What other information would you want to collect to be more confident that you had cloned the SUR gene?	Reference

PART III INFORMATION PATHWAYS 24 Genes and Chromosomes 979 25 DNA Metabolism 1009 26 RNA Metabolism 1057

The third and final part of this book explores the biochemical mechanisms underlying the apparently contradictory requirements for both genetic continuity and the evolution of living organisms. What is the molecular nature of genetic material? How is genetic information transmitted from one generation to the next with high fidelity? How do the rare changes in genetic material that are the raw material of evolution arise? How is genetic information ultimately expressed in the amino acid sequences of the astonishing variety of protein molecules in a living cell? Today's understanding of information pathways has arisen from the convergence of genetics, physics, and chemistry in modern biochemistry. This was epitomized by the discovery of the double-helical structure of DNA, postulated by James Watson and Francis Crick in 1953 (see Fig. 8-13). Genetic theory contributed the concept of coding by genes. Physics permitted the determination of molecular structure by x-ray diffraction analysis. Chemistry revealed the composition of DNA. The profound impact of the Watson-Crick hypothesis arose from its ability to account for a wide range of observations derived from studies in these diverse disciplines. This revolutionized our understanding of the structure of DNA and inevitably stimulated questions about its function. The double-helical structure itself clearly suggested how DNA might be copied so that the information it contains can be transmitted from one generation to the next. Clarification of how the information in DNA is converted into functional proteins came with

27 Protein Metabolism 1103 28 Regulation of Gene Expression 1155

the discovery of messenger RNA and transfer RNA and with the deciphering of the genetic code. These and other major advances gave rise to the central dogma of molecular biology, comprising the three major processes in the cellular utilization of genetic information. The first is replication, the copying of parental DNA to form daughter DNA molecules with identical nucleotide sequences. The second is transcription, the process by which parts of the genetic message encoded in DNA are copied precisely into RNA. The third is translation, whereby the genetic message encoded in messenger RNA is translated on the ribosomes into a polypeptide with a particular sequence of amino acids. Replication DNA Transcription

RNA Translation Protein The central dogma of molecular biology, showing the general pathways of information flow via replication, transcription, and translation. The term “dogma” is a misnomer and is retained for historical reasons only. Introduced by Francis Crick at a time when little evidence supported these ideas, the dogma has become a well-established principle. 977

PART III

978 Information Pathways Part III explores these and related processes. In Chapter 24 we examine the structure, topology, and packaging of chromosomes and genes. The processes underlying the central dogma are elaborated in Chapters 25 through 27. Finally, we turn to regulation, examining how the expression of genetic information is controlled (Chapter 28). A major theme running through these chapters is the added complexity inherent in the biosynthesis of macromolecules that contain information. Assembling nucleic acids and proteins with particular sequences of nucleotides and amino acids represents nothing less than preserving the faithful expression of the template upon which life itself is based. We might expect the formation of phosphodiester bonds in DNA or peptide bonds in proteins to be a trivial feat for cells, given the arsenal of enzymatic and chemical tools described in Part II. However, the framework of patterns and rules established in our examination of metabolic pathways thus far must be enlarged considerably to take into account molecular information. Bonds must be formed between particular subunits in informational biopolymers, avoiding either the occurrence or the persistence of sequence errors. This has an enormous impact on the thermodynamics, chemistry, and enzymology of the biosynthetic processes. Formation of a peptide bond requires an energy input of only about 21 kJ/mol of bonds and can be catalyzed by relatively simple enzymes. But to synthesize a bond between two specific amino acids at a particular point in a polypeptide, the cell invests about 125 kJ/mol while making use of more than 200 enzymes, RNA molecules, and specialized proteins. The chemistry involved in peptide bond formation does not change because of this requirement, but additional processes are layered over the basic reaction to ensure that the peptide bond is formed between particular amino acids. Biological information is expensive. The dynamic interaction between nucleic acids and proteins is another central theme of Part III. Regulatory and catalytic RNA molecules are gradually taking a more prominent place in our understanding of these pathways (discussed in Chapters 26 and 27). However, most of the processes that make up the pathways of cellular information flow are catalyzed and regulated by proteins. An understanding of these enzymes and other proteins can have practical as well as intellectual rewards, because they form the basis

of recombinant DNA technology (introduced in Chapter 9). Evolution again constitutes an overarching theme. Many of the processes outlined in Part III can be traced back billions of years, and a few can be traced to LUCA, the last universal common ancestor. The ribosome, most of the translational apparatus, and some parts of the transcriptional machinery are shared by every living organism on this planet. Genetic information is a kind of molecular clock that can help define ancestral relationships among species. Shared information pathways connect humans to every other species now living on Earth, and to all species that came before. Exploration of these pathways is allowing scientists to slowly open the curtain on the first act—the events that may have heralded the beginning of life on Earth.

biological puzzle. Given that these molecules are generally much longer than the cells or viral particles that contain them (Fig. 24-1), how do they fit? The size of DNA molecules presents an interesting 0.5 μm FIGURE 24-1 Bacteriophage T2 protein coat surrounded by its single, linear molecule of DNA. The DNA was released by lysing the bacteriophage particle in distilled water and allowing the DNA to spread on the water surface. An undamaged T2 bacteriophage particle consists of a head structure that tapers to a tail by which the bacteriophage attaches itself to the outer surface of a bacterial cell. All the DNA shown in this electron micrograph is normally packaged inside the phage head. into their cellular or viral packages? To address this question, we shift our focus from the secondary structure of DNA, considered in Chapter 8, to the extraordinary degree of organization required for the tertiary packaging of DNA into chromosomes—the repositories of genetic information. The chapter begins with an examination of the elements that make up viral and cellular chromosomes, and then considers chromosomal size and organization. We then discuss DNA topology, describing the coiling and supercoiling of DNA molecules. Finally, we consider the protein-DNA interactions that organize chromosomes into compact structures.

24.1 Chromosomal Elements

Cellular DNA contains genes and intergenic regions, both of which may serve functions vital to the cell. The more complex genomes, such as those of eukaryotic cells, demand increased levels of chromosomal organization, and this is reflected in the chromosomes' structural features. We begin by considering the different types of DNA sequences and structural elements within chromosomes. Genes Are Segments of DNA That Code for Polypeptide Chains and RNAs Our understanding of genes has evolved tremendously over the last century. Classically, a gene was defined as a portion of a chromosome that determines or affects a single character or phenotype (visible property), such as eye color. George Beadle and Edward Tatum proposed a molecular definition of a gene in 1940. After exposing spores of the fungus *Neurospora crassa* to x rays and other agents now known to damage DNA and cause alterations in DNA sequence (mutations), they detected mutant fungal strains that lacked one or another specific enzyme,

sometimes resulting in the failure of an entire metabolic pathway. Beadle and Tatum concluded that a gene is a segment of genetic material that determines, or codes for, one enzyme: the 979

24

1980 Genes and Chromosomes one gene-one enzyme hypothesis. Later this concept was broadened to one gene-one polypeptide, because many genes code for a protein that is not an enzyme or for one polypeptide of a multisubunit protein. AMR) George W. Beadle, Edward L. Tatum, 1903-1989 1909-1975 The modern biochemical definition of a gene is even more precise. A gene is all the DNA that encodes the primary sequence of some final gene product, which can be either a polypeptide or an RNA with a structural or catalytic function. DNA also contains other segments or sequences that have a purely regulatory function. Regulatory sequences provide signals that may denote the beginning or the end of genes, or influence the transcription of genes, or function as initiation points for replication or recombination (Chapter 28). Some genes can be expressed in different ways to generate multiple gene products from a single segment of DNA. The special transcriptional and translational mechanisms that allow this are described in Chapters 26 through 28. We can estimate directly the minimum overall size of genes that encode proteins. As described in detail in Chapter 27, each amino acid of a polypeptide chain is coded for by a sequence of three consecutive nucleotides in a single strand of DNA (Fig. 24-2), with these “codons” arranged in a sequence that corresponds to the sequence of amino acids in the polypeptide that the gene encodes. A polypeptide chain of 350 amino acid residues (an average-size chain) corresponds to 1,050 bp of DNA. Many genes in eukaryotes and a few in bacteria and archaea are interrupted by noncoding DNA segments and are therefore considerably longer than this simple calculation would suggest. How many genes are in a single chromosome? The *Escherichia coli* chromosome, one of the bacterial genomes that have been completely sequenced, is a circular DNA molecule (in the sense of an endless loop rather than a perfect circle) with 4,639,675 bp. These base pairs encode about 4,300 genes for proteins and another 157 genes for structural or catalytic RNA molecules. Among eukaryotes, the approximately 3.1 billion base pairs of the human genome include approximately 25,000 genes on the 24 different chromosomes. FIGURE 24-2 Colinearity of the coding nucleotide sequences of DNA and mRNA and the amino acid sequence of a polypeptide chain. The triplets of nucleotide units in DNA determine the amino acids in a protein through the intermediary mRNA. One of the DNA strands serves as a template for synthesis of mRNA, which has nucleotide triplets (codons) complementary to those of the DNA. In some bacterial and many eukaryotic genes, coding sequences are interrupted at intervals by regions of noncoding sequences (called introns).

DNA Molecules Are Much Longer Than the Cellular or Viral Packages That Contain Them Chromosomal DNAs are often many orders of magnitude longer than the cells or viruses in which they are located (Fig. 24-1; Table 24-1). This is true of every class of organism or viral parasite.

Viruses Viruses are not free-living organisms; rather, they are infectious parasites that use the resources of a host cell to carry out many of the processes they require to propagate. Many viral particles consist of no more than a genome (usually a single RNA or DNA molecule) surrounded by a protein coat. Almost all plant viruses and some bacterial and animal viruses have RNA genomes. These genomes tend to be particularly small. For example, the genomes of mammalian retroviruses such as HIV are about 9,000 nucleotides long, and the genome of the bacteriophage QB has 4,220 nucleotides. Both types of virus have singlestranded RNA genomes.

24.1 Chromosomal Elements 981 EUGI 7S The Sizes of DNA and Viral Particles for Some Bacterial Viruses (Bacteriophages)

Size of viral particle (nm)	Length of Long dimension of Virus DNA (bp)	viral DNA (nm)
bX174	5,386	1,939
25 EA	39,936	14,377
78 A (lambda)	48,502	17,460
190 T4	168,889	60,800
210 Note:		

Data on size of DNA are for the replicative form (double-stranded). The contour length is calculated assuming that each base pair occupies a length of 3.4 Å (see Fig. 8-13). The genomes of DNA viruses vary greatly in size (Table 24-1). Many viral DNAs are circular for at least part of their life cycle. During viral replication within a host cell, specific types of viral DNA called replicative forms may appear; for example, many linear DNAs become circular and all single-stranded DNAs become double-stranded. A typical medium-size DNA virus is bacteriophage A (lambda), which infects *E. coli*. In its replicative form inside cells, A DNA is a circular double helix. This double-stranded DNA contains 48,502 bp and has a contour length of 17.5 μm. Bacteriophage X174 is a much smaller DNA virus; the DNA in the viral particle is a single-stranded circle, and the doublestranded replicative form contains 5,386 bp. Although viral genomes are small, the contour lengths of their DNAs are typically hundreds of times longer than the long dimensions of the viral particles that contain them (Table 24-1). Bacteria A single *E. coli* cell contains almost 100 times as much DNA as a bacteriophage A particle. The chromosome of an *E. coli* cell is a single double-stranded circular DNA molecule. Its 4,639,675 bp have a contour length of about 1.7 mm, some 850 times the length of the *E. coli* cell (Fig. 24-3). In addition to the very large, circular DNA chromosome in their nucleoid, many bacteria contain one or more small circular DNA molecules that are free in the cytosol. These extrachromosomal elements are called plasmids (Fig. 24-4; see also p. 317). Most plasmids are only a few thousand base pairs long, but some contain more than 10,000 bp. They carry genetic information and undergo replication to yield daughter plasmids, which pass into the daughter cells at cell division. Plasmids have been found in yeast and other fungi as well as in bacteria. In many cases plasmids confer no obvious advantage on their host, and their sole function seems to be self-propagation. However, some plasmids carry genes that are useful to the host bacterium. For example, some plasmid genes make a host bacterium

resistant to antibacterial agents. Plasmids carrying the gene for the enzyme B-lactamase confer resistance to B-lactam antibiotics such as penicillin, ampicillin, and amoxicillin (see Fig. 6-31). These and similar plasmids may pass from an antibiotic-resistant cell to an antibiotic-sensitive cell of the same or another bacterial species, making the recipient cell antibiotic resistant. The extensive use of antibiotics in some human populations has served as a strong selective force, encouraging the spread of antibiotic resistance—coding plasmids (as well as transposable elements, described below, that harbor similar genes) in disease-causing bacteria. Physicians are becoming increasingly reluctant to prescribe antibiotics unless a clear clinical need is confirmed. For similar reasons, the widespread use of antibiotics in animal feeds is being curbed.

Eukaryotes A yeast cell, one of the simplest eukaryotes, has 2.6 times more DNA in its genome than an *E. coli* cell (Table 24-2). Cells of *Drosophila*, the fruit fly used in classical genetic studies, contain more than 35 times as much DNA as *E. coli* cells, and human cells have almost 700 times as much. The cells of many plants and amphibians contain even more. The genetic material of eukaryotic cells is apportioned into chromosomes, the diploid (2n) number depending on the species (Table 24-2). A human somatic cell, for example, has 46 chromosomes (Fig. 24-5). Each chromosome of a eukaryotic cell, such as that shown in Figure 24—5a, contains a single, very large, duplex DNA molecule. The DNA molecules in the 24 different types of human chromosomes (22 matching pairs plus the X and Y sex chromosomes) vary in length over a 25-fold range. Each type of chromosome in eukaryotes carries a characteristic set of genes. The DNA molecules of one human genome (22 chromosomes plus X and Y or two X chromosomes), placed end to end, would extend for about a meter. Most human cells are diploid, and each cell contains a total of 2n of DNA. An adult human body contains approximately 10^{14} cells and thus a total DNA length of 2×10^{14} km. Compare this with the circumference of the earth (4×10^4 km) or the distance between the earth and the sun (1.5×10^8 km)—a dramatic illustration of the extraordinary degree of DNA compaction in our cells.

Note: This information is constantly being refined. For the most current information, consult the websites for the individual genome projects. *The diploid chromosome number is given for all eukaryotes except yeast. †Haploid chromosome number. Wild yeast strains generally have eight (octoploid) or more sets of these chromosomes. ‡Number for females, with two X chromosomes. Males have an X but no Y, thus 11 chromosomes in all.

(b) 24.1 Chromosomal Elements 983 FIGURE 24-5

Eukaryotic chromosomes. (a) A pair of linked and condensed sister chromatids of a human chromosome. Eukaryotic chromosomes are in this state after replication at metaphase during mitosis. (b) A complete set of chromosomes from a leukocyte from one of the authors. There are 46 chromosomes in every (a) Eukaryotic cells also have organelles, mitochondria (Fig. 24-6) and chloroplasts, that contain DNA. Mitochondrial DNA (mtDNA) molecules are much smaller than the nuclear chromosomes. In animal cells, mtDNA contains fewer than 20,000 bp (16,569 bp FIGURE 24-6 A dividing mitochondrion. Some mitochondrial proteins and RNAs are encoded by one of the copies of the mitochondrial DNA (none of which are visible here). The DNA (mtDNA) is replicated each time the mitochondrion divides, before cell division. normal human somatic cell. in human mtDNA) and is a circular duplex. Each mitochondrion typically has 2 to 10 copies of this mtDNA molecule, and the number can rise to hundreds in certain cells of an embryo that is undergoing cell differentiation. In a few organisms (trypanosomes, for example) each mitochondrion contains thousands of copies of mtDNA, organized into a complex and interlinked matrix known as a kinetoplast. Plant cell mtDNA ranges in size from 200,000 to 2,500,000 bp. Chloroplast DNA (cpDNA) also exists as circular duplexes and ranges in size from 120,000 to 160,000 bp. The evolutionary origin of mitochondrial and chloroplast DNAs has been the subject of much speculation. A widely accepted view is that they are vestiges of the chromosomes of ancient bacteria that gained access to the cytoplasm of host cells and became the precursors of these organelles (see Fig. 1-38). Mitochondrial DNA codes for the mitochondrial tRNAs and rRNAs and for a few mitochondrial proteins. More than 95% of mitochondrial proteins are encoded by nuclear DNA. Mitochondria and chloroplasts divide when the cell divides. Their DNA is replicated before and during division, and the daughter DNA molecules pass into the daughter organelles.

FIGURE 24-7 Introns in two eukaryotic genes. The gene for ovalbumin has seven introns (A to G), splitting the coding sequences into eight exons (L, and 1 to 7). The gene for the B subunit of hemoglobin has two Eukaryotic Genes and Chromosomes Are Very Complex Many bacterial species have only one chromosome per cell and, in nearly all cases, each chromosome contains only one copy of each gene. A very few genes, such as those for rRNAs, are repeated several times. Genes and regulatory sequences account for almost all the DNA in bacteria. Moreover, almost every gene is precisely colinear with the amino acid sequence (or RNA sequence) for which it codes (Fig. 24-2). The organization of genes in eukaryotic DNA is structurally and functionally much more complex. The study of eukaryotic chromosome structure, and more recently the sequencing of entire eukaryotic genomes, has yielded many surprises. Many, if not most, eukaryotic genes have a distinctive and puzzling structural feature: their nucleotide sequences contain one or more intervening segments of DNA that do not code for the amino acid sequence of the polypeptide product. These nontranslated inserts interrupt the otherwise colinear relationship between the nucleotide sequence of the gene and the amino acid sequence of the polypeptide it encodes. Such nontranslated DNA segments in genes are called intervening sequences or introns, and the coding segments are called exons. Few bacterial genes contain introns. In higher eukaryotes, the typical gene has much more intron sequence than sequences devoted to exons. For example, in the gene coding for the single polypeptide chain of ovalbumin, an avian egg protein (Fig. 24—7), the introns are much longer than the exons; altogether, seven introns make up 85% of the gene's DNA. The gene for the muscle protein titin is the intron champion, with 178 introns. Genes for histones seem to have no introns. In most cases the function of introns is not clear. In total, only about 1.5% of human DNA is "coding" or exon DNA, carrying information for protein products. However, when the much larger introns are included in the count, as much as 30% of the human genome consists of genes. A great deal of work remains to be done to understand the other genomic sequences. Much of the DNA that is not within genes is made up of repeated sequences of

several kinds. These include transposable elements (transposons), molecular parasites that account for nearly half of the DNA in the human genome (see Fig. 9-29 and Chapters 25 and 26). Introns and three exons, including one intron that alone contains more than half the base pairs of the gene. Approximately 3% of the human genome consists of highly repetitive sequences, also referred to as simple-sequence DNA or simple sequence repeats (SSR). These short sequences, generally less than 10 bp long, are sometimes repeated millions of times per cell. The simple-sequence DNA has also been called satellite DNA, so named because its unusual base composition often causes it to migrate as “satellite” bands (separated from the rest of the DNA) when fragmented cellular DNA samples are centrifuged in a cesium chloride density gradient. Studies suggest that simple-sequence DNA does not encode proteins or RNAs. Unlike the transposable elements, the highly repetitive DNA can have identifiable functional importance in human cellular metabolism, because much of it is associated with two defining features of eukaryotic chromosomes: centromeres and telomeres. The centromere (Fig. 24-8) is a sequence of DNA that functions during cell division as an attachment point for proteins that link the chromosome to the mitotic spindle. This attachment is essential for the equal and orderly distribution of chromosome sets to daughter cells. The centromeres of *Saccharomyces cerevisiae* have been isolated and studied. The sequences essential to centromere function are about 130 bp long and are very rich in A = T pairs. The centromeric sequences of higher eukaryotes are much longer and, unlike those of yeast, generally contain simple-sequence DNA, which consists of thousands of tandem copies of one or a few short sequences of 5 to 10 bp, in the same orientation. The precise role of simple-sequence DNA in centromere function is not yet understood. Telomeres (Greek telos, “end”) are sequences at the ends of eukaryotic chromosomes that help stabilize the chromosome. Telomeres end with multiple repeated sequences of the form 6) (PGy)n B)ALy)n Telomere Centromere Telomere Unique sequences (genes), dispersed repeats, and multiple replication origins

 thermophila (TTGGGG),, (ciliated protozoan) Saccharomyces
 cerevisiae (yeast) Arabidopsis thaliana (plant) ((TG) $1-3$ (TG) $2-3$) n
 TCC where x and y are generally between 1 and 4 (Table 24-3). The
 number of telomere repeats, n, is in the range of 20 to 100 for most
 single-celled eukaryotes and is generally more than 1,500 in
 mammals. The ends of a linear DNA molecule cannot be routinely
 replicated by the cellular replication machinery (which may be one
 reason why bacterial DNA molecules are circular). Repeated
 telomeric sequences are added to eukaryotic chromosome ends
 primarily by the enzyme telomerase (see Fig. 26-38). Artificial
 chromosomes (Chapter 9) have been constructed as a means of
 better understanding the functional significance of many structural
 features of eukaryotic chromosomes. A reasonably stable artificial
 linear chromosome requires only three components: a centromere, a
 telomere at each end, and sequences that allow the initiation of
 DNA replication. Yeast artificial chromosomes (YACs; see Fig. 9-6)
 have been developed as a research tool in biotechnology. Similarly,
 human artificial chromosomes (HACs) are being developed for the
 treatment of genetic diseases. These may eventually provide a new
 path to the intracellular replacement of missing or defective gene
 products or somatic gene therapy.

SUMMARY 24.1 Chromosomal Elements

- > Genes are segments of a chromosome that contain the information for a functional polypeptide or RNA molecule. In addition to genes, chromosomes contain a variety of regulatory sequences involved in replication, transcription, and other processes.
- > Genomic DNA and RNA molecules are generally orders of magnitude longer than the viral particles or cells that contain them.
- > Many genes in eukaryotic cells (but few in bacteria and archaea) are interrupted by noncoding sequences, or introns. The coding segments separated by introns are called exons.
- > Only about 1.5% of human genomic DNA encodes proteins. Even when introns are included, less than one-third of human genomic DNA consists of genes. Much of the remainder consists of repeated sequences of various types. Nucleic acid parasites known as transposons account for about half of the human genome.

24.2 DNA Supercoiling

985 > Eukaryotic chromosomes have two important special-function repetitive DNA sequences: centromeres, which are

attachment points for the mitotic spindle, and telomeres, located at the ends of chromosomes.

24.2 DNA Supercoiling

Cellular DNA, as we have seen, is extremely compacted, implying a high degree of structural organization. The folding mechanism not only must pack the DNA but also must permit access to the information in the DNA. Before considering how this is accomplished in processes such as replication and transcription, we need to examine an important property of DNA structure known as supercoiling. “Supercoiling” means the coiling of a coil. An old-fashioned telephone cord, for example, is typically a coiled wire. The path taken by the wire between the base of the phone and the receiver often includes one or more supercoils (Fig. 24—9). DNA is coiled in the form of a double helix, with both strands of the DNA coiling around an axis. The further coiling of that axis upon itself (Fig. 24-10) produces DNA supercoiling. As detailed below, DNA supercoiling is generally a manifestation of structural strain. When there is no net bending of the DNA axis upon itself, the DNA is said to be in a relaxed state.

Supercoil **FIGURE 24-9 Supercoils.** A typical phone cord is coiled like a DNA helix, and the coiled cord can itself coil in a supercoil. The illustration is especially appropriate because an examination of phone cords helped lead Jerome Vinograd and his colleagues to the insight that many properties of small circular DNAs can be explained by supercoiling. They first detected DNA supercoiling—in small circular viral DNAs—in 1965.

DNA supercoil **FIGURE 24-10 Supercoiling of DNA.** When the axis of the DNA double helix is coiled on itself, it forms a new helix (superhelix). The DNA superhelix is usually called a supercoil. We might have predicted that DNA compaction involved some form of supercoiling. Perhaps less predictable is that replication and transcription of DNA also affect and are affected by supercoiling. Both processes require a separation of DNA strands—a process complicated by the helical interwinding of the strands (as demonstrated in Fig. 24-11). That a DNA molecule would bend on itself and become supercoiled in tightly packaged cellular DNA would seem logical, then, and perhaps even trivial, were it not for one additional fact: many circular DNA molecules remain highly supercoiled even after they are extracted and purified, freed from protein and other cellular components. This indicates that supercoiling is an intrinsic property of DNA tertiary structure. It occurs in all cellular DNAs and is highly regulated by each cell. Several measurable properties of supercoiling have been established, and the study of supercoiling has provided many insights into DNA structure and function. This work has drawn heavily on concepts derived from a branch of mathematics called topology, the study of the properties of an object that do not change under continuous deformations. For DNA, continuous deformations include conformational changes due to thermal motion or an interaction with proteins or other molecules; discontinuous deformations involve DNA strand breakage. For circular DNA molecules, a topological property is one that is unaffected by deformations of the DNA strands as long as no breaks are introduced. Topological properties are changed only by breakage and rejoining of the backbone of one or both DNA strands. We now examine the fundamental properties and physical basis of supercoiling. (a) (b) Underwound DNA polymerase Direction of transcription PWUNE OT aa rne Snout Yi IcpHauun anu UansUipuU YN DINA supercoiling. Because DNA is a double-helical structure, strand separation leads to added stress and supercoiling if the DNA is constrained (not free to rotate) ahead of the strand separation. (a) The general effect can be illustrated by twisting two strands of a rubber band about each other to form a double helix. If one end is constrained, separating the two strands at the other end will lead to

twisting. (b) In a DNA molecule, the progress of a DNA polymerase or RNA polymerase (as shown here) along the DNA involves separation of the strands. As a result, the DNA becomes overwound ahead of the enzyme (upstream) and underwound behind it (downstream). Red arrows indicate the direction of winding. Most Cellular DNA Is Underwound To understand supercoiling, we must first focus on the properties of small circular DNAs such as plasmids and small viral DNAs. When these DNAs have no breaks in either strand, they are referred to as closed-circular DNAs. If the DNA of a closed-circular molecule conforms

24.2 DNA Supercoiling 987 **FIGURE 24-12** Relaxed and supercoiled plasmid DNAs. The molecule in the leftmost electron micrograph is relaxed; the degree of supercoiling increases from left to right. closely to the B-form structure (the Watson-Crick structure; see Fig. 8-13), with one turn of the double helix per 10.5 bp, the DNA is relaxed rather than supercoiled (Fig. 24-12). Supercoiling results when DNA is subject to some form of structural strain. Purified closed-circular DNA is rarely relaxed, regardless of its biological origin. Furthermore, DNAs derived from a given cellular source have a characteristic degree of supercoiling. DNA structure is therefore strained in a manner that is regulated by the cell to induce the supercoiling. In almost every instance, the strain is a result of underwinding of the DNA double helix in the closed circle. In other words, the DNA has fewer helical turns than would be expected for the B-form structure. The effects of underwinding are summarized in Figure 24-13. An 84 bp segment of a circular DNA in the relaxed state would contain eight double-helical turns, or one for every 10.5 bp. If one of these turns were removed, there would be $(84 \text{ bp})/7 = 12.0 \text{ bp}$ per turn, rather than the 10.5 found in B-DNA (Fig. 24-13b). This is a deviation from the most stable DNA form, and the molecule is thermodynamically strained as a result. Generally, much of this strain would be accommodated by coiling the axis of the DNA on itself to form a supercoil (Fig. 24-13c; some of the strain in this 84 bp segment would simply become dispersed in the untwisted structure of the larger DNA molecule). In principle, the strain could also be accommodated by separating the two DNA strands over a distance of about 10 bp (Fig. 24-13d). In isolated closed-circular DNA, strain introduced by underwinding is generally accommodated by supercoiling rather than strand separation, because coiling the axis of the DNA usually requires less energy than breaking the hydrogen bonds that stabilize paired bases. Note, however, that the underwinding of DNA in vivo makes separation of the DNA strands easier, facilitating access to the information they contain. Every cell actively underwinds its DNA with the aid of enzymatic processes (described below), and the resulting strained state represents a form of stored energy. Cells maintain DNA in an underwound state to facilitate its compaction by coiling. The underwinding of DNA is also important to enzymes of DNA metabolism that must bring about strand separation as part of their

function. The underwound state can be maintained only if the DNA is a closed circle or if it is bound and stabilized by proteins so that the strands are not free to rotate about each other. If there is a break in one strand of an isolated, protein-free circular DNA, free rotation at that point will cause the underwound DNA to revert spontaneously to the relaxed state. In a closed-circular DNA molecule, however, the number of helical turns cannot be changed without at least transiently breaking one of i (a) Relaxed (8 turns) - ANON IK™YDCL IDL (b) Strained (7 turns) (c) Supercoil (d) Strand separation

FIGURE 24-13 Effects of DNA underwinding. (a) A segment of DNA in a closed-circular molecule, 84 bp long, in its relaxed form with eight helical turns. (b) Removal of one turn induces structural strain. (c) The strain is generally accommodated by formation of a supercoil. (d) DNA underwinding also makes the separation of strands somewhat easier. In principle, each turn of underwinding should facilitate strand separation over about 10 bp, as shown. However, the hydrogen-bonded base pairs would generally preclude strand separation over such a short distance, and the effect becomes important only for longer DNAs and higher levels of DNA underwinding.

FIGURE 24-14 Linking number, Lk . Here, as usual, each blue ribbon represents one strand of a double-stranded DNA molecule. For the molecule in (a), $Lk = 1$. For the molecule in (b), $Lk = 6$. One of the strands in (b) is kept untwisted for illustrative purposes, to define the border of an imaginary surface (shaded blue). The number of times the twisting strand penetrates this surface provides a rigorous definition of linking number. the DNA strands. The number of helical turns in a DNA molecule therefore provides a precise description of supercoiling. DNA Underwinding Is Defined by Topological Linking Number The field of topology provides some ideas that are useful to the discussion of DNA supercoiling, particularly the concept of linking number. Linking number is a topological property of double-stranded DNA, because it does not vary when the DNA is bent or deformed, as long as both DNA strands remain intact. Linking number (Lk) is illustrated in Figure 24-14. Let's begin by visualizing the separation of the two strands of a double-stranded circular DNA. If the two strands are linked as shown in Figure 24-14a, they are effectively joined by what can be described as a topological bond. Even if all hydrogen bonds and base-stacking interactions were abolished such that the strands were not in physical contact, this topological bond would still link the two strands. Visualize one of the circular strands as the boundary of a surface (such as a soap film spanning the space framed by a circular wire before you blow a soap bubble). The linking number can be defined as the number of times the second strand pierces this surface. For the molecule in Figure 24-14a, $Lk = 1$; for that in Figure 24-14b, $Lk = 6$. The linking number for a closed-circular DNA is always an integer. By convention, if the links between two DNA strands are arranged so that the strands are interwound in a right-handed helix, the linking number is defined as positive (+); for strands interwound in a left-handed helix, the linking number is negative (—). Negative linking numbers are, for all practical purposes, not encountered in DNA. y break (b) Lk undefined $S_4 =$ hs (a) $Lk = 200 =$. (c) $Lk = 198$ FIGURE 24-15 Linking number applied to closed-circular DNA molecules. A 2,100 bp circular DNA is shown in three forms: (a) relaxed, $Lk = 200$; (b) relaxed with a nick (break) in one strand, Lk undefined; and (c) underwound by two turns, $Lk = 198$. The underwound molecule generally exists as

a supercoiled molecule, but underwinding also facilitates the separation of DNA strands. We can now extend these ideas to a closed-circular DNA with 2,100 bp (Fig. 24-15a). When the molecule is relaxed, the linking number is simply the number of base pairs divided by the number of base pairs per turn, which is close to 10.5; so in this case, $Lk = 200$. For a circular DNA molecule to have a topological property such as linking number, neither strand may contain a break. If there is a break in either strand, the strands can, in principle, be unraveled and separated completely. In this case, no topological bond exists and Lk is undefined (Fig. 24-15b). We can now describe DNA underwinding in terms of changes in the linking number. The linking number in relaxed DNA, Lk_p , is used as a reference. For the molecule shown in Figure 24-15a, $Lk = 200$; if two turns are removed from this molecule, $Lk = 198$. The change can be described by the equation $\Delta Lk = Lk - Lk_o = 198 - 200 = -2$. It is often convenient to express the change in linking number in terms of a quantity that is independent of the length of the DNA molecule. This quantity, called the specific linking difference or superhelical density (σ), is a measure of the number of turns removed relative to the number present in relaxed DNA: $\sigma = \Delta Lk / Lk_o$. In the example in Figure 24-15c, $\sigma = -0.01$, which means that 1% (2 of 200) of the helical turns present in the DNA (in its B form) have been removed. The degree

(24-1) (24-2)

Relaxed DNA $Lk = 200$ $\Delta Lk = J$ is $= +2$ Negative Positive supercoils supercoils $Lk = 198$ $Lk = 202$ FIGURE 24-16 Negative and positive supercoils. For the relaxed DNA molecule of Figure 24-15a, underwinding or overwinding by two helical turns ($Lk = 198$ or 202) will produce negative or positive supercoiling, respectively. Note that the DNA axis twists in opposite directions in the two cases. of underwinding in cellular DNAs generally falls in the range of 5% to 7%; that is, $\Delta = -0.05$ to -0.07 . The negative sign indicates that the change in linking number is due to underwinding of the DNA. The supercoiling induced by underwinding is therefore defined as negative supercoiling. Conversely, under some conditions DNA can be overwound, resulting in positive supercoiling. Note that the twisting path taken by the axis of the DNA helix when the DNA is underwound (negative supercoiling) is the mirror image of that taken when the DNA is overwound (positive supercoiling) (Fig. 24-16). Supercoiling is not a random process; the path of the supercoiling is largely prescribed by the torsional strain imparted to the DNA by decreasing or increasing the linking number relative to B-DNA. Linking number can be changed by $+1$ by breaking one DNA strand, rotating one of the ends 360° about the unbroken strand, and rejoining the broken ends. This change has no effect on the number of base pairs or the number of atoms in the circular DNA molecule. Two forms of a circular DNA that differ only in a topological property such as linking number are referred to as topoisomers. WORKED EXAMPLE 24-1 Calculation of Superhelical Density What is the superhelical density (σ) of a closed-circular DNA with a length of 4,200 bp and a linking number (Lk) of 374? What is the superhelical density of the same DNA when $Lk = 412$? Are these molecules negatively or positively supercoiled? Solution: First, calculate Lk_0 by dividing the length of the closed-circular DNA (in bp) by 10.5 bp/turn: $(4,200 \text{ bp}) / (10.5 \text{ bp/turn}) = 400$. We can now calculate ΔLk from Equation 24-1: $\Delta Lk = Lk - Lk_0 = 374 - 400 = -26$. Substituting the values for ΔLk and Lk_0 into Equation 24.2 DNA Supercoiling 989 Straight ribbon (relaxed DNA) Large writhe, small change in twist B $\rightarrow$ S a a Zero writhe, large change in twist FIGURE 24-17 Ribbon model for illustrating twist and writhe. The tan ribbon represents the axis of a relaxed DNA molecule. Strain introduced by twisting the ribbon (underwinding

the DNA) can be manifested as writhe or twist. Topological changes in linking number are usually accompanied by geometric changes in both writhe and twist. 24-2: $\sigma = \Delta Lk / Lk_0 = -26/400 = -0.065$. Since the superhelical density is negative, this DNA molecule is negatively supercoiled. When the same DNA molecule has an Lk of 412, $\Delta Lk = 412 - 400 = 12$ and $\sigma = 12/400 = 0.03$. The superhelical density is positive, and the molecule is positively supercoiled. Linking number can be broken down into two structural components, twist (Tw) and writhe (Wr) (Fig. 24-17). These are more difficult to describe than linking number, but writhe may be thought of as a measure of the coiling of the helix axis, and twist as determining the local twisting or spatial relationship of neighboring base pairs. When the linking number changes, some of the resulting strain is usually compensated for by writhe (supercoiling) and some by changes in twist, giving rise to the equation $Lk = Tw + Wr$. Tw and Wr need not be integers. Twist and writhe are geometric rather than topological properties, because they may be changed by deformation of a closed circular DNA molecule. In addition to causing supercoiling and making strand separation somewhat easier, the underwinding of DNA facilitates structural changes in the molecule. These are of less physiological importance but help illustrate the effects of underwinding. Recall that a cruciform (see Fig. 8-19) generally contains a few unpaired bases; DNA underwinding helps to maintain the required strand separation (Fig. 24-18). Underwinding of a right-handed DNA helix also facilitates the formation of short stretches of left-handed Z-DNA in regions where the base sequence is consistent with the Z form (see Chapter 8). Topoisomerases Catalyze Changes in the Linking Number of DNA DNA supercoiling is a precisely regulated process that influences many aspects of DNA metabolism. Every cell

990 Genes and Chromosomes Cruciform DNA FIGURE

24-18 Promotion of cruciform structures by DNA underwinding. In principle, cruciforms can form at palindromic sequences (see Fig. 8-19), but they seldom occur in relaxed DNA because the linear DNA accommodates more paired bases than does the cruciform structure. Underwinding of the DNA facilitates the partial strand separation needed to promote cruciform formation at appropriate sequences. has enzymes with the sole function of underwinding and/ or relaxing DNA. The enzymes that increase or decrease the extent of DNA underwinding are topoisomerases; the property of DNA that they change is the linking number. These enzymes play an especially important role in processes such as replication and DNA packaging. There are two classes of topoisomerases. Type I topoisomerases act by transiently breaking one of the two DNA strands, passing the unbroken strand through the break and rejoining the broken ends; they change Lk in increments of 1. Type II topoisomerases break both DNA strands and change Lk in increments of 2. The effects of these enzymes can be demonstrated with agarose gel electrophoresis (Fig. 24-19). A population of identical plasmid DNAs with the same linking number migrates as a discrete band during electrophoresis. Topoisomers with Lk values differing by as little as 1 can be separated by this method, so changes in linking number induced by topoisomerases are readily detected. *E. coli* has at least four individual topoisomerases C through IV). Those of type I (topoisomerases I and HI) generally relax DNA by removing negative supercoils (increasing Lk). The way in which bacterial type I topoisomerases change linking number is illustrated in Figure 24-20. A bacterial type II enzyme, called either topoisomerase II or DNA gyrase, can introduce negative 1 2 3 Relaxed — DNA Decreasing Lk Highly supercoiled — DNA FIGURE 24-19 Visualization of topoisomers. In this experiment, all DNA molecules have the same number of base pairs but exhibit some range in he degree of supercoiling. Because supercoiled DNA molecules are more compact than relaxed molecules, they migrate more rapidly during ge electrophoresis. The gels shown here separate topoisomers (moving rom top to bottom) over a limited range of superhelical density. In lane 1, highly supercoiled DNA migrates in a single band, even though differen opoisomers are probably present. Lanes 2 and 3 illustrate the effect

o reating the supercoiled DNA with a type I topoisomerase; the DNA in lane 3 was treated for a longer time than that in lane 2. As the superhelical density of the DNA is reduced to the point where it corresponds to the range in which the gel can resolve individual topoisomers, distinct bands appear. Individual bands in the region indicated by the bracket next to lane 3 each contain DNA circles with the same linking number; the linking number changes by 1 from one band to the next. supercoils (decrease Lk). It uses the energy of ATP to accomplish this. To alter DNA linking number, type II topoisomerases cleave both strands of a DNA molecule and pass another duplex through the break. The degree of supercoiling of bacterial DNA is maintained by regulation of the net activity of topoisomerases I and II. Eukaryotic cells also have type I and type II topoisomerases. The type I enzymes are topoisomerases I and III; the single type II enzyme has two isoforms in vertebrates, called IIA and IIB. Most of the type II enzymes, including a DNA gyrase in archaea, are related and define a family called type IIA. Archaea also have an unusual enzyme, topoisomerase VI, which alone defines the type IIB family. The eukaryotic type II topoisomerases cannot underwind DNA (introduce negative supercoils), but they can relax both positive and negative supercoils (Fig. 24-21). As we will show in the next few chapters, topoisomerases play a critical role in every aspect of DNA metabolism. As a consequence, they are important drug targets for the treatment of bacterial infections and cancer (Box 24-1). DNA Compaction Requires a Special Form of Supercoiling Supercoiled DNA molecules are uniform in a number of respects. The supercoils are right-handed in a negatively supercoiled DNA molecule (Fig. 24-16), and they

Two ATPs are bound and hydrolyzed during this cycle. The enzyme structure and use of ATP are specific to this reaction.

992 Genes and Chromosomes The topological state of cellular DNA is intimately connected with its function. Without topoisomerases, cells cannot replicate or package their DNA, or express their genes—and they die. Inhibitors of topoisomerases have therefore become important pharmaceutical agents, targeted at infectious agents and malignant cells. Two classes of bacterial topoisomerase inhibitors have been developed as antibiotics. The coumarins, including novobiocin and coumermycin A1, are natural products derived from *Streptomyces* species. They inhibit the ATP binding of the bacterial type II topoisomerases, DNA gyrase and topoisomerase IV. These antibiotics are not often used to treat infections in humans, but research continues to identify clinically effective variants. The quinolone antibiotics, also inhibitors of bacterial DNA gyrase and topoisomerase IV, first appeared in 1962 with the introduction of nalidixic acid. This compound had limited effectiveness and is no longer used clinically in the United States, but the continued development of this class of drugs eventually led to the introduction of the fluoroquinolones, exemplified by ciprofloxacin (Cipro). The quinolones act by blocking the last step of the topoisomerase reaction, the resealing of the DNA strand breaks. Ciprofloxacin is a wide-spectrum antibiotic. It is one of the few antibiotics that tend to be extended and narrow rather than compacted, often with multiple branches (Fig. 24-22). At the superhelical densities normally encountered in cells, the length of the supercoil axis, including branches, is about 40% of the length of the DNA. This type of supercoiling is referred to as plectonemic (from the Greek *plektos*, “twisted,” and *nema*, “thread”). This term can be applied to any structure with strands intertwined in some simple and regular way, and it is a good

description of the general structure of supercoiled DNA in solution. LLLP SALES À FIGURE 24-22 Plectonemic supercoiling. present at elevated levels in tumor cells, and agents targeted to these enzymes are much more toxic to the tumors than to most other tissue types. Inhibitors of both type I and type II topoisomerases have been developed as anticancer drugs. Camptothecin, isolated from a Chinese ornamental tree and first tested clinically in the 1970s, is an inhibitor of eukaryotic type I topoisomerases. Clinical (0) OH (0) OH Stee. O (0) OH O H,C~ NH, OH O we o S CH,O~ \~ ~ocH, OH Etoposide Plectonemic supercoiling, the form observed in isolated DNAs in the laboratory, does not produce sufficient compaction to package DNA in the cell. A second form of supercoiling, solenoidal (Fig. 24-23), can be adopted by an underwound DNA. Instead of the extended right-handed supercoils characteristic of the plectonemic form, solenoidal supercoiling involves tight left-handed turns, similar to the shape taken up by a garden hose neatly wrapped on a reel. Although their structures are dramatically different, plectonemic and solenoidal supercoiling are two forms of negative supercoiling that can be taken up by the same segment of underwound DNA. The two forms are readily interconvertible. Although the plectonemic form is more stable in solution, the solenoidal form can be stabilized by protein binding as it is in eukaryotic chromosomes. It provides a much greater degree of compaction (Fig. 24-23). Solenoidal supercoiling is the mechanism by which underwinding contributes to DNA compaction.

24.2 DNA Supercoiling

993 trials indicated limited effectiveness, despite its early promise in preclinical work on mice. However, two effective derivatives, irinotecan (Campto) and topotecan (Hycamtin)—used to treat colorectal cancer and ovarian cancer, respectively—were developed in the 1990s. Additional derivatives are likely to be approved for clinical use in the coming years. All of these drugs act by trapping the topoisomerase-DNA complex in which the DNA is cleaved, inhibiting religation. The human type II topoisomerases are targeted by a variety of antitumor drugs, including doxorubicin (Adriamycin), etoposide (Etopophos), and ellipticine. Doxorubicin, effective against several kinds of human tumors, is an anthracycline in clinical use. Most of these drugs stabilize the covalent topoisomerase-DNA (cleaved) complex. All of these anticancer agents generally increase the levels of DNA damage in the targeted, rapidly growing tumor cells. However, noncancerous tissues can also be affected, leading to a more general

toxicity and unpleasant side effects that must be managed during therapy. As cancer therapies become more effective and survival statistics for cancer patients improve, the independent appearance of new tumors is becoming a greater problem. In the continuing search for new cancer therapies, the topoisomerases are likely to remain prominent targets for research. CH; Q y N aA H CH, Ellipticine

SUMMARY 24.2 DNA Supercoiling

- > Most cellular DNAs are supercoiled. Underwinding decreases the total number of helical turns in the DNA relative to the relaxed, B form. To maintain an underwound state, DNA must be either a closed circle or bound to protein. Underwinding is quantified by a topological parameter called linking number, Lk .
- > Underwinding is measured in terms of specific linking difference, σ (also called superhelical density), which is $(Lk - Lk_0)/Lk_0$. For cellular DNAs, σ is typically -0.05 to -0.07 , which means that approximately 5% to 7% of the helical turns in the DNA have been removed. DNA underwinding facilitates strand separation by enzymes of DNA metabolism.
- > DNAs that differ only in linking number are called topoisomers. Enzymes that underwind

FIGURE 24-23 Plectonemic and solenoidal supercoiling of the same DNA molecule, drawn to scale. Plectonemic supercoiling takes the form of extended right-handed coils. Solenoidal negative supercoiling takes the form of tight left-handed turns about an imaginary tubelike structure. The two forms are readily interconverted, although the solenoidal form is generally not observed unless certain proteins are bound to the DNA. Solenoidal supercoiling provides a much greater degree of compaction. and/or relax DNA, the topoisomerases, catalyze changes in linking number. The two classes of topoisomerases, type I and type II, change Lk in increments of 1 or 2, respectively, per catalytic event. 24.3 The Structure of Chromosomes The term “chromosome” is used to refer to a nucleic acid molecule that is the repository of genetic information in a virus, a bacterium, a eukaryotic cell, or an organelle. It also refers to the densely colored bodies seen in the nuclei of dye-stained eukaryotic cells, as visualized using a light microscope. Chromatin Consists of DNA and Proteins The eukaryotic cell cycle (see Fig. 12-44) produces remarkable changes in the structure of chromosomes (Fig. 24-24). In nondividing eukaryotic cells (in G₀) and those in interphase (G₁, S, and G₂), the chromosomal material, chromatin, is amorphous and seems to be randomly dispersed in certain parts of the nucleus. In the S phase of interphase the DNA in this amorphous state replicates, each chromosome producing two sister chromosomes (called sister chromatids) that remain associated with each other after replication is complete. The chromosomes become much more condensed during prophase of mitosis, taking the form of a species-specific number of well-defined pairs of sister chromatids (Fig. 24-5). Chromatin consists of fibers containing protein and DNA in approximately equal proportions (by mass), along with a small amount of RNA. The DNA in the chromatin is very tightly associated with proteins called histones, which package and order the DNA into structural units called nucleosomes (Fig. 24-25). Also found in chromatin are many nonhistone proteins, some of which help maintain chromosome structure Metaphase Anaphase Mitosis

FIGURE 24-24 Changes in chromosome structure during the

eukaryotic cell cycle. The relative lengths of the phases shown here are for convenience only. The duration of each phase varies with cell type and growth conditions (for single-celled organisms) or metabolic state (for multicellular organisms); mitosis is typically the shortest. Cellular DNA is uncondensed throughout interphase, as shown in the cartoons of the nucleus in the diagram. The interphase period can be divided (see Fig. 12-44) into the G₁ (gap) phase; the S (synthesis) phase, when the DNA is replicated; and the G₂ phase, throughout which the replicated chromosomes (chromatids) cohere to each other. Mitosis can be divided into four stages. The DNA undergoes condensation in prophase. During metaphase, the condensed chromosomes line up in pairs along the plane halfway between the spindle poles. The two chromosomes of each pair are linked to different spindle poles via microtubules that extend between the spindle and the centromere. The sister chromatids separate at anaphase, each drawn toward the spindle pole to which it is connected. The process is completed in telophase. After cell division is complete, the chromosomes decondense and the cycle begins anew.

(a) Histone core of nucleosome = Linker DNA of f nucleosome 50 nm

FIGURE 24-25 Nucleosomes. (a) Regularly spaced nucleosomes consist of core histone proteins bound to DNA. (b) In this electron micrograph, the DNA-wrapped histone octamer structures are clearly visible. and others that regulate the expression of specific genes (Chapter 28). Beginning with nucleosomes, eukaryotic chromosomal DNA is packaged into a succession of higher-order structures that ultimately yield the compact chromosome seen with the light microscope. We now turn to a description of this structure in eukaryotes and compare it with the packaging of DNA in bacterial cells.

Histones Are Small, Basic Proteins Found in the chromatin of all eukaryotic cells, histones have molecular weights between 11,000 and 21,000 and are very rich in the basic amino acids arginine and lysine (together these make up about one-fourth of the amino acid residues). All eukaryotic cells have five major classes of histones, differing in molecular weight and amino acid composition (Table 24-4). The H3 histones | **TABLE 24-4 | E Types and Properties of the Common Histones** 995

24.3 The Structure of Chromosomes are nearly identical in amino acid sequence in all eukaryotes, as are the H4 histones, suggesting strict conservation of their functions. For example, only 2 of 102 amino acid residues differ between the H4 histone molecules of peas and cows, and only 8 differ between the H4 histones of humans and yeast. Histones H1, H2A, and H2B show less sequence similarity among eukaryotic species. Each type of histone is subject to enzymatic modification by methylation, acetylation, ADP-ribosylation, phosphorylation, glycosylation, sumoylation, or ubiquitination. Such modifications affect the net electric charge, shape, and other properties of histones, as well as the structural and functional properties of the chromatin, and they play a role in the regulation of transcription. In addition, eukaryotes generally have several variant forms of certain histones, most notably histones H2A and H3, described in more detail below. The variant forms, along with their modifications, have specialized roles in DNA metabolism.

Nucleosomes Are the Fundamental Organizational Units of Chromatin The eukaryotic chromosome depicted in Figure 24-5 represents the compaction of a DNA molecule about 10^6 μm long into a cell nucleus that is typically 5 to 10 μm in diameter. This compaction is achieved by means of

several levels of highly organized folding. Subjection of chromosomes to treatments that partially unfold them reveals a structure in which the DNA is bound tightly to beads of protein, often regularly spaced. The beads in this “beads-on-a-string” arrangement are complexes of histones and DNA. The bead plus the connecting DNA that leads to the next bead form the nucleosome, the fundamental unit of organization on which the higher-order packing of chromatin is built (Fig. 24-26). The bead of each nucleosome contains eight histone molecules: two copies each of H2A, H2B, H3, and H4. The spacing of the nucleosome beads provides a repeating unit typically of about 200 bp, of which 146 bp are bound tightly around the eight-part histone core and the remainder serve as linker DNA between nucleosome beads. Histone H1 binds to the linker DNA. (b) A ribbon representation of the nucleosome from the African frog *Xenopus laevis*. Different colors represent the different histones, matching the colors in (a). (c) Surface representation of the nucleosome. The view in (c) is rotated relative to the view in (b) to match the orientation shown above in (a). A 146 bp segment of DNA in the form of a left-handed solenoidal supercoil wraps around the histone complex 1.67 times. (d) Two views of histone amino-terminal tails protruding from between the two DNA duplexes that supercoil around the nucleosome. Some tails pass between the supercoils through holes formed by alignment of the minor grooves of adjacent helices. The H3 and H2B tails emerge between the two coils of DNA wrapped around the histone; the H4 and H2A tails emerge between adjacent histone subunits. (e) The amino-terminal tails of one nucleosome extrude from the particle and interact with adjacent nucleosomes, helping to define higher-order DNA packaging, in the form of a left-handed solenoidal supercoil (Fig. 24-26). Extending out from the nucleosome core are the amino-terminal tails of the histones, which are intrinsically disordered (Fig. 24—26d). Most of the histone modifications occur in these tails. The tails, in turn, play a key role in forming contacts between nucleosomes in the chromatin (Fig. 24-26e). A close inspection of this structure reveals why eukaryotic DNA is underwound even though eukaryotic cells lack enzymes that underwind DNA. Recall that the solenoidal wrapping of DNA in nucleosomes is but one form of supercoiling that can be taken up by underwound (negatively supercoiled) DNA. The tight wrapping of DNA around the histone core requires the removal of about one helical turn in the DNA. When the protein core of a nucleosome binds in vitro to a relaxed, closed-circular DNA, the binding introduces a negative supercoil. Because this binding process does (d) ~ Histone tails

Front view Side view (e) DNA Amino-terminal Histone tails octamer

not break the DNA or change the linking number, the formation of a negative solenoidal supercoil must be accompanied by a compensatory positive supercoil in the unbound region of the DNA (Fig. 24-27). As mentioned earlier, eukaryotic topoisomerases can relax positive supercoils. Relaxing the unbound positive supercoil

leaves the negative supercoil fixed (through its binding to the nucleosome histone core) and results in an overall decrease in linking number. Indeed, topoisomerases have proved necessary for assembling chromatin from purified histones and closed-circular DNA in vitro. Another factor that affects the binding of DNA to histones in nucleosome cores is the sequence of the bound DNA. Histone cores do not bind at random positions on the DNA; rather, some locations are more likely to be bound than others. This positioning is not fully understood but in some cases seems to depend on a

 supercoil (ALk = -1). local abundance of A=T base pairs in the
 DNA helix where it is in contact with the histones (Fig. 24-28). A
 cluster of two or three A=T base pairs facilitates the compression
 of the minor groove that is needed for the DNA to wrap tightly
 around the nucleosome's histone core. Nucleosomes bind
 particularly well to sequences where AA or AT or TT dinucleotides
 are staggered at 10 bp intervals, an arrangement that can account
 for up to 50% of the positions of bound histones in vivo. Other
 proteins are required for the positioning of some nucleosome cores
 on DNA. In several organisms, certain proteins bind to a specific
 DNA sequence and facilitate the formation of a nucleosome core
 nearby. Nucleosomes are deposited on the DNA during replication,
 or following other processes that require a transient displacement of
 nucleosomes. Nucleosomes seem to be deposited in a stepwise
 manner. A tetramer of two H3 and two H4 histones binds first,
 followed by H2A-H2B dimers. The incorporation of nucleosomes
 into chromosomes after chromosomal replication is mediated by a
 complex of histone chaperones that include proteins known as
 chromatin assembly factor 1 (CAF1), RTT106 (regulation of Ty1
 transposition), and anti-silencing factor 1 (ASF1). 24.3 The

 effect of DNA sequence on nucleosome binding. (PDB ID 1A01)
 Runs of two or more A=T base pairs facilitate the bending of DNA,
 while runs of two or more G=C base pairs have the opposite effect.
 When spaced at about 10 bp intervals, consecutive A=T base pairs

help bend DNA into a circle. When consecutive G = C base pairs are spaced 10 bp apart, and offset by 5 bp from runs of A = T base pairs, DNA binding to the chromosome is facilitated. These bind to acetylated variants of histones H3 and H4. The mechanism of nucleosome deposition is not understood in detail, although parts of this complex are known to directly interact with parts of the replication machinery. Some of the same histone chaperones, or different ones, may help assemble nucleosomes after DNA repair, transcription, or other processes. Histone exchange factors permit the substitution of histone variants for core histones in some contexts. Proper placement of these variant histones is important. Studies have shown that mice lacking one of these variant histones die as early embryos (Box 24-2). Precise positioning of nucleosome cores also plays a role in the expression of some eukaryotic genes (Chapter 28).

Nucleosomes Are Packed into Successively Higher-Order Structures

Wrapping of DNA around a nucleosome core compacts the DNA length about sevenfold. The overall compaction in a chromosome, however, is greater than 10,000-fold— ample evidence for even higher orders of structural organization. In chromosomes isolated by very gentle methods, nucleosome cores seem to be organized into a

998 Genes and Chromosomes Information that is passed from one generation to the next—to daughter cells at cell division or from parent to offspring—but is not encoded in DNA sequences is referred to as epigenetic information. Much of it is in the form of covalent modification of histones and/or the placement of histone variants in chromosomes. The chromatin regions where active gene expression (transcription) is occurring tend to be partially decondensed and are called euchromatin. In these regions, histones H3 and H2A are often replaced by the histone variants H3.3 and H2AZ, respectively (Fig. 1). The complexes that deposit nucleosomes containing histone variants on the DNA are similar to those that deposit nucleosomes with the more common histones. Nucleosomes containing histone H3.3 are deposited by a complex in which chromatin assembly factor 1 (CAF1) is replaced by the protein HIRA (the name is derived from a class of proteins called HIR, for histone repressor). Both CAF1 and HIRA can be considered histone chaperones, helping to ensure the proper assembly and placement of nucleosomes. Histone H3.3 differs in sequence from H3 by only four amino acid residues, but these residues all play key roles in histone deposition. Like histone H3.3, H2AZ is associated with a distinct nucleosome deposition complex, and it is generally associated with chromatin regions involved in active transcription. Incorporation of H2AZ stabilizes the nucleosome octamer, but impedes some cooperative interactions between nucleosomes that are needed to compact the chromosome. This leads to a more open chromosome structure that facilitates the expression of genes in the region where H2AZ is located. The gene encoding H2AZ is essential in mammals. In fruit flies, loss of H2AZ prevents development beyond the larval stages. Another H2A variant is H2AX, which is associated with DNA repair and genetic recombination. In mice, the absence of H2AX results in genome instability and male infertility. Modest amounts of H2AX seem to be scattered throughout the genome. When a double-strand break occurs, nearby molecules of H2AX become phosphorylated at Ser¹³⁹ in the carboxylterminal region. If this phosphorylation is blocked experimentally, formation of the protein complexes necessary for DNA repair is inhibited. structure called the 30 nm fiber (Fig. 24-29). This packing includes one molecule of histone H1 per nucleosome core. Two current models for the organization of histones and DNA in 30 nm fibers

are presented in Figure 24-29. Organization into 30 nm fibers does not extend over the entire chromosome but is punctuated by regions bound by sequence-specific (nonhistone) DNA-binding proteins. The 30 nm structure also seems BOX 24-2 Mitotic Epigenetics, Nucleosome Structure, and Histone Variants The H3 histone variant known as CENPA is associated with the repeated DNA sequences in centromeres. The chromatin in the centromere region contains the histone chaperones CAF 1 and HIRA, and both proteins could be involved in the deposition of nucleosomes containing CENPA. Elimination of the gene for CENPA is lethal in mice. The function and positioning of the histone variants can be studied by an application of technologies used in genomics. One useful technology is chromatin immunoprecipitation, or chromatin IP (ChIP). Nucleosomes containing a particular histone variant are precipitated by an antibody that binds specifically to this variant. These nucleosomes can be studied in isolation from their DNA, but more commonly the DNA associated with them is included in the study to determine where the nucleosomes of interest bind. The DNA can be labeled and used to probe a microarray (see Fig. 9-23), yielding a map of genomic sequences to which (a: KG) CH3) |@® CHR] (CHR CH3 H3 E =z HED CH3 CH3 CH3 H3.3 HFD H2A n HFD aj 2AX Es HFD m 2A7 M HED = ©) H2B [7 HFD SS] : CH3 CH3 | | H4 | I HED i |

FIGURE 1 Several variants of histones H3, H2A, and H2B are known. Shown here are the core histones and a few of the known variants. HFD denotes the histone-fold domain, a structural domain common to all core histones. to depend on the transcriptional activity of the particular region of DNA. Regions in which genes are being transcribed are apparently in a less-ordered state that contains little, if any, histone H1. The 30 nm fiber—a second level of chromatin organization—provides an approximately 100-fold compaction of the DNA. The higher levels of folding are not yet understood, but certain regions of DNA

those particular nucleosomes bind. Because microarrays are often referred to as chips, this technique is called a ChIP-chip experiment (Fig. 2). The histone variants, along with the many covalent modifications that histones undergo, help define and isolate the functions of chromatin. The histone modifications do not disappear at cell division or during meiosis, and thus they become part of the information transmitted from one generation to the next in all eukaryotic organisms. f fa N le) Gene annotation

FIGURE 2 A ChIP-chip experiment is designed to reveal the genomic DNA sequences to which a particular histone variant binds. (a) A hisone variant with an epitope tag (a protein or chemical structure recognized by an antibody; see Chaptes 5 and 9) is introduced into a particular cell type, where it is incorporated into nucleosomes. (In some cases, an epitope tag is unnecessary because antibodies may be available that bind directly to the histone modification of interest.) Chromain is isolated from the cells and digested briefly with micrococcal nuclease (MNase). The DNA bound by nucleosomes is protected from digestion, but the linker DNA is cleaved, releasing segments of DNA bound to one or two nucleosomes. An antibody that binds to the epitope tag is added, and the nucleosomes containing the epitope-tagged histone variant are selectively precipitated. The DNA in these nucleosomes is extracted from the precipitate, labeled, and used to probe a microarray representing all or selected parts of the genomic sequences of that particular cell type. (b) In this example, the binding of histone H3.3 is characterized in a short segment of chromosome 2L from seem to associate with a chromosomal scaffold (Fig. 24-30). The scaffold-associated regions are separated by loops of DNA with perhaps 20 to 100 kbp. The DNA ina loop

may contain a set of related genes. The scaffold itself may contain several proteins, notably topoisomerase II and SMC proteins, described below. The presence of topoisomerase II further emphasizes the relationship between DNA underwinding and chromatin structure. *a. e. eo Drosophila melanogaster*. Numbers at the top correspond to numbered nucleotide positions in this chromosome arm. Each spot in the microarray represents 100 bp of genomic sequence, so the data here represent more than 1700 separate spots in the microarray. At each spot, the signal from the labeled DNA that was precipitated with antibody to histone H3.3 is presented as a ratio of that signal relative to the control signal generated when total genomic DNA is isolated without immunoprecipitation, sheared, labeled with a different color of label, and used to probe the same microarray. Signals above the horizontal line indicate genomic positions where histone H3.3 binding is enriched relative to the control. Signals below the line are regions where histone H3.3 is relatively absent. Annotated (known) genes in this segment of the genome are shown in the bottom panel (thickened bars). Bars above the line are genes transcribed 5' to 3' left to right, and boxes below the line are transcribed right to left. Red bars are genes where RNA polymerase II is also abundant, indicating active transcription. The histone H3.3 binding is concentrated in and near these genes undergoing active transcription. Topoisomerase II is so important to the maintenance of chromatin structure that inhibitors of this enzyme can kill rapidly dividing cells. Several drugs used in cancer chemotherapy are topoisomerase II inhibitors that allow the enzyme to promote strand breakage but not the resealing of the breaks (see Box 24-1). Evidence exists for additional layers of organization in eukaryotic chromosomes, each dramatically enhancing

FIGURE 24-29 The 30 nm fiber, a higher-order organization of nucleosomes. The compact fiber is formed by the tight packing of nucleosomes. (a) The 30 nm fiber, as seen by electron microscopy. There are two proposed models for the structure that are consistent with available data: (b) the solenoid model featuring one helical array of nucleosomes and (c) the zigzag model featuring two helical arrays of nucleosomes wrapped about each other. The black line is intended only to trace the proposed general path of the organized structure. the degree of compaction. One model for achieving this compaction is illustrated in Figure 24-31. Higherorder chromatin structure probably varies from chromosome to chromosome, from one region to the next in a single chromosome, and from moment to moment in the life of a cell. No single model can adequately describe these structures. Nevertheless, the principle is clear: DNA compaction in eukaryotic chromosomes is likely to involve coils upon coils upon coils . . . é

ThreeDimensional Packaging of Nuclear Chromosomes Condensed Chromosome Structures Are Maintained by SMC Proteins A third major class of chromatin proteins, in addition to the histones and topoisomerases, is the SMC proteins (structural maintenance of chromosomes). The primary structure of SMC proteins consists of five distinct domains (Fig. 24-32a). The amino- and carboxylterminal globular domains, N and C, each of which contains part of an ATP-hydrolytic site, are connected by two regions of α -helical coiled-coil motifs (see Fig. 4-11) that are joined by a hinge domain. The proteins are generally dimeric, forming a V-shaped complex that is thought to be tied together through the protein's hinge domains (Fig. 24-32b). One N and one C domain come together to form a complete ATP-hydrolytic site at each free end of the V. Proteins in the SMC family are found in all types of organisms, from bacteria to humans. Eukaryotes have two major types, cohesins and condensins, both of which are bound by regulatory and accessory proteins (Fig. 24-32c). The cohesins play a substantial role in linking together sister chromatids immediately after replication and keeping them together as the chromosomes condense to metaphase. This linkage is essential if chromosomes are to segregate properly at cell division. The cohesins, along with a

third protein, kleisin, are thought to form a ring around the replicated chromosomes that

1002 Genes and Chromosomes Condensin Chromatin [are hydrolysis Intramolecular chromosome looping ie bindin E wawan M |Prophase Prophase FIGURE 24-33 The possible role of condensins in chromatin condensation. Initially, the DNA is bound at the hinge region of the SMC protein, in the interior of what can become an intramolecular SMC ring. ATP binding leads to head-to-head association, forming supercoiled loops in the bound DNA. Subsequent rearrangement of the head-to-head interactions to form rosettes condenses the DNA. Condensins may organize the looping of the chromosome segments in a number of ways. Two current models are shown. ties them together until separation is required at cell division. The ring may expand and contract in response to ATP hydrolysis. The condensins are essential to the condensation of chromosomes as cells enter mitosis. In the laboratory, condensins bind to DNA in a manner that creates positive supercoils; that is, condensin binding causes the DNA to become overwound, in contrast to the underwinding induced by the binding of nucleosomes. One model for the role of condensins in chromatin compaction is presented in Figure 24-33. The cohesins and condensins are essential in orchestrating the many changes in chromosome structure during the eukaryotic cell cycle (Fig. 24-34). Bacterial DNA Is Also Highly Organized We now turn briefly to the structure of bacterial chromosomes. Bacterial DNA is compacted in a structure called the nucleoid, which can occupy a significant fraction of the cell volume (Fig. 24-35). The DNA seems to be attached at one or more points to the inner surface of the plasma membrane. Much less is known about the structure of the nucleoid than of eukaryotic chromatin, but a complex organization is slowly being revealed. chromosomes return to the uncondensed state.

2 μ m FIGURE 24-35 *E. coli* nucleoids. The DNA of these cells is stained with a dye that fluoresces when exposed to UV light. The light area defines the nucleoid. Note that some cells have replicated their DNA but have not yet undergone cell division and hence have multiple nucleoids. seems to organize the circular chromosome into a series of about 500 looped domains, each encompassing 10,000 bp on average (Fig. 24-36), as described above for chromatin. The domains are topologically constrained; for example, if the DNA is cleaved in one domain, only the DNA within that domain will be relaxed. The domains do not have fixed end points. Instead, the boundaries are most likely in constant motion along the DNA, coordinated with DNA replication. Bacterial DNA does not seem to have any structure comparable to the local organization provided by nucleosomes in eukaryotes. Histone-like proteins are abundant in *E. coli*—the best-characterized example is a two-subunit protein called HU (M, 19,000)—but these proteins bind and dissociate within minutes, and no regular, stable DNA-histone structure has been found. The dynamic structural changes in the bacterial chromosome may reflect a requirement for more ready access to its genetic information. The bacterial cell division cycle can be as short as 15 min, whereas a typical eukaryotic cell may not divide for hours or even months. In addition, a much greater fraction of bacterial DNA is used to encode RNA and/or protein products. Higher rates of cellular metabolism in bacteria mean that a much higher proportion of the DNA is being transcribed or replicated at a given time than in most eukaryotic cells. With this overview of the complexity of DNA structure, we are now ready to turn, in the next chapter, to a discussion of DNA metabolism.

SUMMARY 24.3 The Structure of Chromosomes > The fundamental unit of organization in the chromatin of eukaryotic cells is the nucleosome, which consists of histones and a 200 bp segment of DNA. A core protein particle containing eight histones (two copies each of histones H2A, H2B, H3, and H4) is encircled by a segment of DNA (about 146 bp) in the form of a left-handed solenoidal supercoil. 24.3 The Structure of Chromosomes 1003 FIGURE 24-36 Looped domains of the *E. coli* chromosome. Each domain is about 10,000 bp in length. The domains are not static, but move along the DNA as replication proceeds. Barriers at the boundaries of the domains, of unknown composition, prevent the relaxation of DNA

beyond the boundaries of the domain where a strand break occurs. The putative boundary complexes are shown as gray-shaded ovoids. The arrows denote movement of DNA through the boundary complexes. > Nucleosomes are organized into 30 nm fibers, and the fibers are extensively folded to provide the 10,000-fold compaction required to fit a typical eukaryotic chromosome into a cell nucleus. The higher-order folding involves attachment to a chromosomal scaffold that contains histone H1, topoisomerase II, and SMC proteins. The SMC proteins, principally cohesins and condensins, play important roles in keeping the chromosomes organized during each stage of the cell cycle. > Bacterial chromosomes are extensively compacted into the nucleoid, but the chromosome seems to be much more dynamic and irregular in structure than eukaryotic chromatin, reflecting the shorter cell cycle and very active metabolism of a bacterial cell. Packaging of DNA in a Virus Bacteriophage T2 has a DNA of molecular weight 120×10^6 contained in a head about 210 nm long. Calculate the length of the DNA (assume the molecular weight of a nucleotide pair is 650) and compare it with the length of the T2 head.

2. The DNA of Phage M13 The base composition of phage M13 DNA is A, 23%; T, 36%; G, 21%; C, 20%. What does this tell you about the DNA of phage M13?

3. The Mycoplasma Genome The complete genome of the simplest bacterium known, *Mycoplasma genitalium*, is a circular DNA molecule with 580,070 bp. Calculate the molecular weight and contour length (when relaxed) of this molecule. What is L_{ko} for the *Mycoplasma* chromosome? If $\sigma = 0.06$, what is L_k ?

4. Size of Eukaryotic Genes An enzyme isolated from rat liver has 192 amino acid residues and is coded for by a gene with 1,440 bp. Explain the relationship between the number of amino acid residues in the enzyme and the number of nucleotide pairs in its gene.

5. Linking Number A closed-circular DNA molecule in its relaxed form has an L_k of 500. Approximately how many base

pairs are in this DNA? How is the linking number altered (increases, decreases, doesn't change, becomes undefined) when (a) a protein complex binds to form a nucleosome, (b) one DNA strand is broken, (c) DNA gyrase and ATP are added to the DNA solution, or (d) the double helix is denatured by heat? 6. DNA Topology In the presence of a eukaryotic condensin and a type II topoisomerase, the Lk of a relaxed closed

circular DNA molecule does not change. However, the DNA becomes highly knotted. condensin type II topoisomerase Formation of the knots requires breakage of the DNA, passage of a segment of DNA through the break, and religation by the topoisomerase. Given that every reaction of the topoisomerase would be expected to result in a change in linking number, how can Lk remain the same? 7. Superhelical Density Bacteriophage A infects *E. coli* by integrating its DNA into the bacterial chromosome. The success of this recombination depends on the topology of the *E. coli* DNA. When the superhelical density (σ) of the *E. coli* DNA is greater than -0.045 , the probability of integration is $< 20\%$; when σ is less than -0.06 , the probability is $\sim 70\%$. Plasmid DNA isolated from an *E. coli* culture is found to have a length of 13,800 bp and an Lk of 1,222. Calculate σ for this DNA and predict the likelihood that bacteriophage A will be able to infect this culture. 8. Altering Linking Number (a) What is the Lk of a 5,000 bp circular duplex DNA molecule with a nick in one strand? (b) What is the Lk of the molecule in (a) when the nick is sealed (relaxed)? (c) How would the Lk of the molecule in (b) be affected by the action of a single molecule of *E. coli* topoisomerase I? (d) What is the Lk of the molecule in (b) after eight enzymatic turnovers by a single molecule of DNA gyrase in the presence of ATP? (e) What is the Lk of the molecule in (d) after four enzymatic turnovers by a single molecule of bacterial type I topoisomerase? (f) What is the Lk of the molecule in (d) after binding of one nucleosome? 9. Chromatin Early evidence that helped researchers define nucleosome structure is illustrated by the agarose gel below, in which the thick bands represent DNA. It was generated by briefly treating chromatin with an enzyme that degrades DNA, then removing all protein and subjecting the purified DNA to electrophoresis. Numbers at the side of the gel denote the position to which a linear DNA of the indicated size would migrate. What does this gel tell you about chromatin structure? Why are the DNA bands thick and spread out rather than sharply defined? 1,000 bp — 800 bp — 600 bp — 400 bp — 200 bp — Problems 1005 10. DNA Structure Explain how the underwinding of a B-DNA helix might facilitate or stabilize the formation of Z-DNA. 11. Maintaining DNA Structure (a) Describe two structural features required for a DNA molecule to maintain a negatively supercoiled

state. (b) List three structural changes that become more favorable when a DNA molecule is negatively supercoiled. (c) What enzyme, with the aid of ATP, can generate negative superhelicity in DNA? (d) Describe the physical mechanism by which this enzyme acts.

12. Yeast Artificial Chromosomes (YACs) YACs are used to clone large pieces of DNA in yeast cells. What three types of DNA sequence are required to ensure proper replication and propagation of a YAC in a yeast cell?

13. Nucleoid Structure in Bacteria In bacteria, the transcription of a subset of genes is affected by DNA topology, with expression increasing or (more often) decreasing when the DNA is relaxed. When a bacterial chromosome is cleaved at a specific site by a restriction enzyme (one that cuts at a long, and thus rare, sequence), only nearby genes (within 10,000 bp) exhibit either an increase or decrease in expression. The transcription of genes elsewhere in the chromosome is unaffected. Explain. (Hint: See Fig. 24-36.)

14. DNA Topology When DNA is subjected to electrophoresis in an agarose gel, shorter molecules migrate faster than longer ones. Closed-circular DNAs of the same size but with different linking numbers also can be separated on an agarose gel: topoisomers that are more supercoiled, and thus more condensed, migrate faster through the gel. In the gel shown below, purified plasmid DNA has migrated from top to bottom. There are two bands, with the faster band much more prominent. (a) What are the DNA species in the two bands? (b) If topoisomerase I is added to a solution of this DNA, what will happen to the upper and lower bands after electrophoresis? (c) If DNA ligase is added to the DNA, will the appearance of the bands change? Explain your answer. (d) If DNA gyrase plus ATP is added to the DNA after the addition of DNA ligase, how will the band pattern change?

15. DNA Topoisomers When DNA is subjected to electrophoresis in an agarose gel, shorter molecules migrate faster than longer ones. Closed-circular DNAs of the same size but different linking number also can be separated on an agarose gel: topoisomers that are more supercoiled, and thus more condensed, migrate faster through the gel—from top to bottom in the gels shown on the right. A dye, chloroquine, was

1006 Genes and Chromosomes added to these gels.

Chloroquine intercalates between base pairs and stabilizes a more underwound DNA structure. When the dye binds to a relaxed closed-circular DNA, the DNA is underwound where the dye binds, and unbound regions take on positive supercoils to compensate. In the experiment shown here, topoisomerases were used to make preparations of the same DNA circle with different superhelical densities (a). Completely relaxed DNA migrated to the position labeled N (for nicked), and highly supercoiled DNA (above the limit where individual topoisomers can be distinguished) to the position labeled X. 0.5 μ g/mL chloroquine Average o g O D A O © OD a SVEI Ho > O 4 fs ϕ Lf L Z N — = = Å- — = ae — | = = _ — = x — & Seance + 4 > 4 > Runs as Runs as + ALk —ALk Gel A 5 μ g/mL chloroquine Bliss o @ & S 9 SOMO DY Zo SES LLA L L = X -> + 4 > + 4 Runs as Runs as + ALk —ALk Gel B (a) In gel A, why does the $\phi = 0$ lane (i.e., DNA prepared so that $\phi = 0$, on average) have multiple bands? (b) In gel B, is the DNA from the $\phi = 0$ preparation positively or negatively supercoiled in the presence of the intercalating dye? (c) In both gels, the $\phi = -0.115$ lane has two bands, one a highly supercoiled DNA and one relaxed. Propose a reason for the presence of relaxed DNA in these lanes (and others). (d) The native DNA (leftmost lane in each gel) is the same DNA circle isolated from bacterial cells and untreated. What is the approximate superhelical density of this native DNA? 16.

Nucleosomes The human genome contains just over 3.1 billion base pairs. Assuming it is covered with nucleosomes that are spaced as described in this chapter, how many molecules of histone H2A are present in one somatic human cell? (Do not consider reductions in H2A due to its replacement in some regions by H2A variants.) How would the number change after DNA replication but before cell division? **Data Analysis Problem 17. Defining the Functional Elements of Yeast Chromosomes** Figure 24-8 shows the major structural elements of a chromosome of baker's yeast (*Saccharomyces cerevisiae*). Heiter, Mann, Snyder, and Davis (1985) determined the properties of some of these elements. They based their study on the finding that in yeast cells, plasmids (which have genes and an origin of replication) act differently from chromosomes (which have these elements plus centromeres and telomeres) during mitosis. The plasmids are not manipulated by the

mitotic apparatus and segregate randomly between daughter cells. Without a selectable marker to force the host cells to retain them (see Fig. 9-4), these plasmids are rapidly lost. In contrast, chromosomes, even without a selectable marker, are manipulated by the mitotic apparatus and are lost at a very low rate (about 10~ per cell division). Heiter and colleagues set out to determine the important components of yeast chromosomes by constructing plasmids with various parts of chromosomes and observing whether these “synthetic chromosomes” segregated properly during mitosis. To measure the rates of different types of failed chromosome segregation, the researchers needed a rapid assay to determine the number of copies of synthetic chromosomes present in different cells. This assay took advantage of the fact that wild-type yeast colonies are white whereas certain adenine-requiring (*ade*) mutants yield red colonies on nutrient media. Specifically, *ade2* cells lack functional AIR carboxylase (the enzyme of step @ in Figure 22-35) and accumulate AIR (5-aminoimidazole ribonucleotide) in their cytoplasm. This excess AIR is converted to a conspicuous red pigment. The other part of the assay involved the gene *SUP11*, which encodes an ochre suppressor (a type of nonsense suppressor; see Box 27-4) that suppresses the phenotype of some *ade2*” mutants. Heiter and coworkers started with a diploid strain of yeast homozygous for *ade2Z*’; these cells are red. When the mutant cells contain one copy of *SUP11*, the metabolic defect is partly suppressed and the cells are pink. When the cells contain two or more copies of *SUP11*, the defect is completely suppressed and the cells are white. The researchers inserted one copy of *SUP*// into synthetic chromosomes containing various elements thought to be important in chromosome function, and then observed how well these chromosomes were passed from one generation to the next. These pink cells were plated on nonselective media, and the behavior of the synthetic chromosomes was observed. Specifically, Heiter and coworkers looked for colonies in which the synthetic chromosomes segregated improperly at the first division after plating, giving rise to a colony that is half one genotype and half the other. Because yeast cells are nonmotile, this will be a sectorized colony, with one half one color and the other half another color.

(a) One way for the mitotic process to fail is nondisjunction: the chromosome replicates but the sister chromatids fail to separate, so both copies of the chromosome end up in the same daughter cell. Explain how nondisjunction of the synthetic chromosome would give rise to a colony that is half red and half white. (b) Another way for the mitotic process to fail is chromosome loss: the chromosome does not enter the daughter nucleus or is not replicated. Explain how loss of the synthetic chromosome would give rise to a colony that is half red and half pink. By counting the frequency of the different colony types, Heiter and colleagues could estimate the frequency of these aberrant mitotic events with different types of synthetic chromosome. First, they explored the requirement for centromeric sequences by constructing synthetic chromosomes with different-sized DNA fragments containing a known centromere. Their results are shown below. Size of centromere Synthetic containing Chromosome Nondisjunction chromosome fragment (kbp) loss (%) (%) 1 none — > 50 2 0.63 1.6 1.1 3 1.6 1.9 0.4 4 3.0 17 0.35 5 6.0 1.6 0.35 (c) Based on these data, what can you conclude about the size of the centromere required for normal mitotic segregation? Explain your reasoning. Data Analysis Problem 1007 (d) Interestingly, all the synthetic chromosomes created in these experiments were circular and lacked telomeres. Explain how they could be replicated more-or-less properly. Heiter and colleagues next constructed a series of linear synthetic chromosomes that included the functional centromeric sequence and telomeres, and measured the total mitotic error frequency (% loss + % nondisjunction) as a function of size: Synthetic Size Total error chromosome (kbp) frequency (%) 6 15 11.0 7 55 1.5 8 95 0.44 9 137 0.14 (e) Based on these data, what can you conclude about the chromosome size required for normal mitotic segregation? Explain your reasoning. (f) Normal yeast chromosomes are linear, range from 250 kbp to 2,000 kbp in length, and have a mitotic error rate of about 10⁻⁴ per cell division. Extrapolating the results from (e), do the centromeric and telomeric sequences used in these experiments explain the mitotic stability of normal yeast chromosomes, or must other elements be involved? Explain your reasoning. (Hint: A plot of log (error rate) vs. length will be helpful.) Reference Heiter, P., Mann, C., Snyder, M., & Davis, R.W. (1985) Mitotic stability of yeast chromosomes: a colony

color assay that measures nondisjunction and chromosome loss. Cell 40, 381-392.

DNA Metabolism 25.1 DNA Replication 1011 25.2

DNA Repair 1027 25.3 DNA Recombination 1038

DNA occupies a unique and central place among biological macromolecules. The nucleotide sequences of DNA encode the primary structures of all cellular RNAs and proteins and, through enzymes, indirectly affect the synthesis of all other cellular constituents. This passage of information from DNA to RNA and protein guides the size, shape, and functioning of every living thing. DNA is a marvelous device for the stable storage of genetic information. The phrase “stable storage,” however, conveys a static and misleading picture. It fails to capture the complexity of processes by which genetic information is preserved in an uncorrupted state and then transmitted from one generation of cells to the next. DNA metabolism comprises both the process that gives rise to faithful copies of DNA molecules (replication) and the processes that affect the inherent structure of the information (repair and recombination). Together, these activities are the focus of this chapter. The metabolism of DNA is shaped by the requirement for an exquisite degree of accuracy. The chemistry of joining one nucleotide to the next in DNA replication is elegant and simple, almost deceptively so. However, as is the case with all information-containing polymers, forming a covalent link between two monomeric units is just a small part of the biochemical process. As we shall see, complexity arises in the form of enzymatic devices to ensure that the correct nucleotide is added and that genetic information is transmitted intact. Uncorrected errors that arise during DNA synthesis can have dire consequences, not only because they can permanently affect or eliminate the function of a gene but also because the change is inheritable. The enzymes that synthesize DNA may copy DNA molecules that contain millions of bases. They do so with extraordinary fidelity and speed, even though the DNA, as the repository of genetic information, occupies a substrate that is highly compacted and bound with other proteins. Formation of phosphodiester bonds to link nucleotides in the backbone of a growing DNA strand is therefore only one part of an elaborate process that requires myriad proteins and enzymes. Maintaining the integrity of genetic information lies at the heart of DNA repair. As detailed in Chapter 8, DNA is susceptible to many types of damaging reactions. Such reactions are infrequent but significant nevertheless, because of the very low biological

tolerance for changes in DNA sequence. DNA is the only macromolecule for which repair systems exist; the number, diversity, and complexity of DNA repair mechanisms reflect the wide range of insults that can harm DNA. Cells can rearrange their genetic information by processes collectively called recombination—seemingly undermining the principle that the stability and integrity of genetic information are paramount. However, most DNA rearrangements in fact play constructive roles in maintaining genomic integrity, contributing in special ways to DNA replication, DNA repair, and chromosome segregation. Special emphasis is given in this chapter to the enzymes of DNA metabolism. They merit careful study not only because of their intrinsic biological importance and interest but also for their increasing importance in medicine and for their everyday use as reagents in a wide range of modern biochemical technologies. Many of the seminal discoveries in DNA metabolism have been made with *Escherichia coli*, so its well-understood enzymes are generally used to illustrate the ground rules. A quick look at some relevant genes on the *E. coli* genetic map (Fig. 25-1) provides just a hint of the complexity of the enzymatic systems involved in DNA metabolism. Before taking a closer look at replication, we must make a short digression into the use of abbreviations in naming bacterial genes and proteins—you will encounter many of these in this and later chapters. Similar conventions exist for naming eukaryotic genes, although the exact form of the abbreviations may vary with the species and no single convention applies to all eukaryotic systems. 1009

 map shows the relative positions of genes encoding many of the
 proteins important in DNA metabolism. The number of genes
 known to be involved provides a hint of the complexity of these
 processes. The numbers 0 to 100 inside the circular chromosome
 denote a genetic measurement called minutes. Each minute
 corresponds to ~40,000 bp along the DNA molecule. The KEY
 CONVENTION: Bacterial genes generally are named using three
 lowercase, italicized letters that often reflect a gene's apparent
 function. For example, the dna, wwr, and vec genes affect DNA
 replication, resistance to the damaging effects of UV radiation, and
 recombination, respectively. Where several genes affect the same
 process, the letters A, B, C, and so forth, are added—as in dnaA,
 dnaB, dnaQ, for example—usually reflecting their order of
 discovery rather than their order in a reaction sequence. W The use
 of abbreviations in naming proteins is less straightforward. During
 genetic investigations, the protein product of each gene is usually
 isolated and characterized {ra Recombination and recombinational
 repair ruvB uvrC DNA repair sbcB Exonuclease | nfo AP
 endonuclease three-letter names of genes and other elements

generally reflect some aspect of their function. These include mut, mutagenesis; dna, DNA replication; pol, DNA polymerase; rpo, RNA polymerase; uvr, UV resistance; rec, recombination; dam, DNA adenine methylation; lig, DNA ligase; Ter, termination of replication; and ori, origin of replication (oriC in *E. coli*, as shown here). Many bacterial genes have been identified and named before the roles of their protein products are understood in detail. Sometimes the gene product is found to be a previously isolated protein, and some renaming occurs. Often, however, the product turns out to be an as yet unknown protein, with an activity not easily described by a simple enzyme name. KEY CONVENTION: Bacterial proteins often retain the name of their genes. When referring to the protein product of an *E. coli* gene, roman type is used and the first letter is capitalized: for example, the dnaA and recA gene products are the DnaA and RecA proteins, respectively.

W

25.1 DNA Replication Long before the structure of DNA was known, scientists wondered at the ability of organisms to create faithful copies of themselves and, later, at the ability of cells to produce many identical copies of large, complex macromolecules. Speculation about these problems centered around the concept of a template, a structure that would allow molecules to be lined up in a specific order and joined to create a macromolecule with a unique sequence and function. The 1940s brought the revelation that DNA was the genetic molecule, but not until James Watson and Francis Crick deduced its structure did the way in which DNA could act as a template for the replication and transmission of genetic information become clear: one strand is the complement of the other. The strict base-pairing rules mean that each strand provides the template for a new strand with a predictable and complementary sequence (see Figs 8-14, 8-15).

Nucleotides: Building Blocks of Nucleic Acids

The fundamental properties of the DNA replication process and the mechanisms used by the enzymes that catalyze it have proved to be essentially identical in all species. This mechanistic unity is a major theme as we proceed from general properties of the replication process, to *E. coli* replication enzymes, and, finally, to replication in eukaryotes.

DNA Replication Follows a Set of Fundamental Rules

Early research on bacterial DNA replication and its enzymes helped to establish several basic properties that have proven applicable to DNA synthesis in every organism.

DNA Replication Is Semiconservative

Each DNA strand serves as a template for the synthesis of a new strand, producing two new DNA molecules, each with one new strand and one old strand. This is semiconservative replication. Watson and Crick proposed the hypothesis of semiconservative replication soon after publication of their 1953 paper on the structure of DNA, and the hypothesis was proved by ingeniously designed experiments carried out by Matthew Meselson and Franklin Stahl in 1957. Meselson and Stahl grew *E. coli* cells for many generations in a medium in which the sole nitrogen source (NH_4Cl) contained ^{15}N , the “heavy” isotope of nitrogen, instead of the normal, more abundant “light” isotope, ^{14}N . The DNA isolated from these cells had a density about 1% greater than that of normal ^{14}N DNA (Fig. 25-2a). Although this is only a small difference, a mixture of heavy ^{15}N DNA and light ^{14}N DNA can be separated by centrifugation to equilibrium in a cesium chloride density gradient.

The *E. coli* cells grown in the N medium were transferred to a fresh medium containing only the ^{14}N . DNA Replication 1011 DNA extracted and centrifuged to equilibrium in CsCl density gradient (a) Heavy DNA (^{15}N) — z Original parent molecule Hybrid DNA (b) ^{15}N - ^{14}N a S S First-generation daughter molecules 25 Second-generation daughter molecules Light DNA (^{14}N) — (c) Hybrid DNA — Gee 0

FIGURE 25-2 The Meselson-Stahl experiment. (a) Cells were grown for many generations in a medium containing only heavy nitrogen, ^{15}N , so that all the nitrogen in their DNA was ^{15}N , as shown by a single band (blue) when centrifuged in a CsCl density gradient. (b) Once the cells had been transferred to a medium containing only light nitrogen, ^{14}N , cellular DNA isolated after one generation equilibrated at a higher position in the density gradient (purple band). (c) A second cycle of replication yielded a hybrid DNA band (purple) and another band (red), containing only ^{14}N DNA, confirming semiconservative replication.

isotope, where they were allowed to grow until the cell population had just doubled. The DNA isolated from these first-generation cells formed a single band in the CsCl gradient at a position indicating that the double-helical DNA molecules of the daughter cells were hybrids containing one new ^{14}N strand and one parent ^{15}N strand (Fig. 25-2b). This result argued against conservative replication, an alternative hypothesis in which one progeny DNA molecule would consist of two newly synthesized DNA strands and the other would contain the two parent strands; this would not yield hybrid DNA molecules in the Meselson-Stahl experiment. The semiconservative replication hypothesis was further supported in the next step of the experiment (Fig. 25-2c). Cells were again allowed to double in number in the ^{14}N medium. The isolated DNA product of this second cycle of replication exhibited two bands in the density gradient, one with a density equal to that of light DNA and the other with the density of the hybrid DNA observed after the first cell doubling.

1012 DNA Metabolism Replication Begins at an Origin and Usually Proceeds Bidirectionally Following the confirmation of a semiconservative mechanism of replication, a host of questions arose. Are the parent DNA strands completely unwound before each is replicated? Does replication begin at random places or at a unique point? After initiation at any point in the DNA, does replication proceed in one direction or both? An early indication that replication is a highly coordinated process in which the parent strands are simultaneously unwound and replicated was provided by John Cairns, using autoradiography. He made *E. coli* DNA radioactive by growing cells in a medium containing thymidine labeled with tritium (H). When the DNA was carefully isolated, spread, and overlaid with a photographic emulsion for several weeks, the radioactive thymidine residues generated “tracks” of silver grains in the emulsion, producing an image of the DNA molecule. These tracks revealed that the intact chromosome of *E. coli* is a single huge circle, 1.7 mm long. Radioactive DNA isolated from cells during replication showed an extra loop (Fig. 25-3). Cairns concluded that the loop resulted from the formation of two radioactive daughter strands, each complementary to a parent strand. One or both ends of the loop are dynamic points, termed replication forks, where parent DNA is being unwound and the separated strands quickly replicated. Cairns’s results demonstrated that both DNA strands are replicated simultaneously, and variations on his experiment indicated that replication of bacterial chromosomes is bidirectional: both ends of the loop have active replication forks. The determination of whether the replication loops originate at a unique point in the DNA required landmarks along the DNA molecule. These were provided by a technique called denaturation mapping, developed by Ross Inman and colleagues. Using the 48,502 bp chromosome of bacteriophage λ , Inman showed that DNA could be selectively denatured at sequences unusually rich in A = T base pairs, generating a reproducible pattern of single-strand bubbles (see Fig. 8-28). Isolated DNA containing replication loops can be partially denatured in the same way. This allows the position and progress of the replication forks to be measured and mapped, using the denatured regions as points of reference. The technique revealed that in this system the replication loops always initiate at a unique

point, which was termed an origin. It also confirmed the earlier observation that replication is usually bidirectional. For circular DNA molecules, the two replication forks meet at a point on the side of the circle opposite to the origin. Specific origins of replication have since been identified and characterized in bacteria and lower eukaryotes. DNA Synthesis Proceeds in a 5'—> 3' Direction and Is Semidiscontinuous A new strand of DNA is always synthesized in the 5'—3' direction, with the free 3' OH as the point at which the DNA is elongated (the 5' and 3' ends of a Parental duplex Replication forks pd Replication Z forks Daughter duplexes

FIGURE 25-3 Visualization of DNA replication. Stages in the replication of circular DNA molecules have been visualized by electron microscopy. Replication of a circular chromosome produces a structure resembling the Greek letter theta, θ , as both strands are replicated simultaneously (new strands shown in light red). The electron micrographs show images of plasmid DNA being replicated from a single replication origin. DNA strands are defined in Fig. 8-7). Because the two DNA strands are antiparallel, the strand serving as the template is read from its 3' end toward its 5' end. If synthesis always proceeds in the 5'—3' direction, how can both strands be synthesized simultaneously? If both strands were synthesized continuously while the replication fork moved, one strand would have to undergo 3'—5' synthesis. This problem was resolved by Reiji Okazaki and colleagues in the 1960s. Okazaki found that one of the new DNA strands is synthesized in short pieces, now called Okazaki fragments. This work ultimately led to the conclusion that one strand is synthesized continuously and the other discontinuously (Fig. 25-4). The continuous strand, or leading strand, is the one in which 5'—3' synthesis proceeds in the same direction as

Leading strand 5' → 3' Okazaki fragments 3' → 5' FIGURE 25-4

Defining DNA strands at the replication fork. A new DNA strand (light red) is always synthesized in the 5' → 3' direction. The template lagging strand is read in the opposite direction, 3' → 5'. The leading strand is continuously synthesized in the direction taken by the replication fork. The other strand, the lagging strand, is synthesized discontinuously in short pieces (Okazaki fragments) in a direction opposite to that in which the replication fork moves. The Okazaki fragments are spliced together by DNA ligase. In bacteria, Okazaki fragments are ~1,000 to 2,000 nucleotides long. In eukaryotic cells, they are 150 to 200 nucleotides long.

replication fork movement. The discontinuous strand, or lagging strand, is the one in which 5' → 3' synthesis proceeds in the direction opposite to the direction of fork movement. Okazaki fragments range in length from a few hundred to a few thousand nucleotides, depending on the cell type. As we shall see later, leading and lagging strand syntheses are tightly coordinated.

DNA Is Degraded by Nucleases To explain the enzymology of DNA replication, we first introduce the enzymes that degrade DNA rather than synthesize it. These enzymes are known as nucleases, or DNases if they are specific for DNA rather than RNA. Every cell contains several different nucleases, belonging to two broad classes: exonucleases and endonucleases. Exonucleases degrade nucleic acids from one end of the molecule. Many operate in only the 5' → 3' or the 3' → 5' direction, removing nucleotides only from the 5' or the 3' end, respectively, of one strand of a double-stranded nucleic acid or of a singlestranded DNA. Endonucleases can begin to degrade at specific internal sites in a nucleic acid strand or molecule, reducing it to smaller and smaller fragments. A few exonucleases and endonucleases degrade only singlestranded DNA. There are a few important classes of endonucleases that cleave only at specific nucleotide sequences (such as the restriction endonucleases that are so important in biotechnology; see Chapter 9, Fig. 9-2). You will encounter many types of nucleases in this and subsequent chapters.

DNA Is Synthesized by DNA Polymerases The search for an enzyme that could synthesize DNA began in 1955. Work by Arthur Kornberg and colleagues 25.1 DNA Replication 1013 led to the purification and characterization of a DNA polymerase from *E. coli* cells, a single-polypeptide enzyme now called DNA polymerase I (M, 103,000;

encoded by the *polA* gene). Much later, investigators found that *E. coli* contains at least four other distinct DNA polymerases, described below. Detailed studies of DNA polymerase I revealed features of the DNA synthetic process that are now known to be common to all DNA polymerases. The fundamental reaction is a phosphoryl group transfer. The nucleophile is the 3'-hydroxyl group of the nucleotide at the 3' end of the growing strand. Nucleophilic attack occurs at the a phosphorus of the incoming deoxynucleoside 5'-triphosphate (Fig. 25-5a). Inorganic pyrophosphate is released in the reaction. The general reaction is Arthur Kornberg, 1918-2007 (dNMP), + dNTP $\rightarrow$ (dNMP),,,; + PP; (25-1) DNA Lengthened DNA where dNMP and dNTP are deoxynucleoside 5'-monophosphate and 5'-triphosphate, respectively. Catalysis by virtually all DNA polymerases prominently involves two Mg^{2+} ions at the active site (Fig. 25-5a). One of these helps to deprotonate the 3'-hydroxyl group, rendering it a more effective nucleophile. The other binds to the incoming dNTP and facilitates departure of the pyrophosphate. The reaction seems to proceed with only a minimal change in free energy, given that one phosphodiester bond is formed at the expense of a somewhat less stable phosphate anhydride. However, noncovalent basestacking and base-pairing interactions provide additional stabilization to the lengthened DNA product relative to the free nucleotide. Also, the formation of products is facilitated in the cell by the 19 kJ/mol generated in the subsequent hydrolysis of the pyrophosphate product by the enzyme pyrophosphatase (p. 524). Early work on DNA polymerase I led to the definition of two central requirements for DNA polymerization (Fig. 25-5). First, all DNA polymerases require a template. The polymerization reaction is guided by a template DNA strand according to the base-pairing rules predicted by Watson and Crick: where a guanine is present in the template, a cytosine deoxynucleotide is added to the new strand, and so on. This was a particularly important discovery, not only because it provided a chemical basis for accurate semiconservative DNA replication but also because it represented the first example of the use of a template to guide a biosynthetic reaction.

1014 DNA Metabolism (a) DNA synthesis Template strand Growing strand (primer) Incoming dNTP (b) Incoming dNTP Primer strand 5' GAAT Insertion site Template strand 3' 3' Postinsertion Insertion site (c) (d) DNA 3' 5' Postinsertion site

Thumb Fingers Second, the polymerases require a primer. A primer is a strand segment (complementary to the template) with a free 3'-hydroxyl group to which a nucleotide can be added; the free 3' end of the primer is called the primer terminus. In other words, part of the new strand must already be in place: all DNA polymerases can only add nucleotides to a preexisting strand. Many primers are oligonucleotides of RNA rather than DNA, and specialized enzymes synthesize primers when and where they are required. A DNA polymerase active site has two parts (Fig. 25-5b). The incoming nucleotide is initially positioned in the insertion site. Once the phosphodiester bond is formed, the polymerase slides forward on the DNA and

MECHANISM FIGURE 25-5 Elongation of a DNA chain. (a) The catalytic mechanism for addition of a new nucleotide by DNA polymerase involves two Mg^{2+} ions, coordinated to the phosphate groups of the incoming nucleotide triphosphate, the 3'-hydroxyl group that will act as a nucleophile, and three residues, two of which are highly conserved in all DNA polymerases. The depicted active site facilitates attack of the 3'-hydroxyl group of the nucleotide triphosphate; the other Mg^{2+} ion facilitates displacement of the pyrophosphate. Both ions stabilize the structure of the covalent transition state. RNA polymerases use a similar mechanism (see 26-1a). (b) DNA polymerase activity also requires a single unpaired strand as template and a primer strand to provide the free hydroxyl group at the 3' end to which the new nucleotide unit is added. Each incoming nucleotide is selected in part by base-pairing to the appropriate nucleotide in the template strand. The reaction produces a 3' end of the primer strand that has a new free 3'-hydroxyl, allowing the addition of another nucleotide. The newly formed base pair migrates to make the active site available to the next pair to be formed. (c) The core of most DNA polymerases is shaped like a human hand that wraps around the active site. The structure shown is the DNA polymerase β of *Thermus aquaticus*, bound to DNA (PDB ID 4KTQ). (d) A cartoon interpretation of the polymerase structure shows the insertion and postinsertion parts of

the active site. The insertion site is where the nucleotide addition occurs, and the postinsertion site is where the newly formed base pair migrates after it appears. é Nucleotide Polymerization by DNA Polymerase Translocation 5/ 34 5 -Insertion site the new base pair is positioned in the postinsertion site. These elements are located in a pocket that resembles the palm of a hand (Fig. 25-5c). After adding a nucleotide to a growing DNA strand, a DNA polymerase either dissociates or moves along the template and adds another nucleotide. Dissociation and reassociation of the polymerase can limit the overall polymerization rate—the process is generally faster when a polymerase adds more nucleotides without dissociating from the template. The average number of nucleotides added before a polymerase dissociates defines its processivity. DNA polymerases vary greatly in processivity; some add just a few nucleotides before dissociating, others add many thousands. Nucleotide Polymerization by DNA Polymerase

Replication Is Very Accurate Replication proceeds with an extraordinary degree of fidelity. In *E. coli*, a mistake is made only once for every 10^9 to 10^{10} nucleotides added. For the *Æ. coli* chromosome of $\sim 4.6 \times 10^9$ bp, this means that an error occurs only once per 1,000 to 10,000 replications. During polymerization, discrimination between correct and incorrect nucleotides relies not just on the hydrogen bonds that specify the correct pairing between complementary bases but also on the common geometry of the standard A = T and G = C base pairs (Fig. 25-6). The active site of DNA polymerase I accommodates only base pairs with this geometry. An incorrect nucleotide may be able to hydrogen-bond with a base in the template, but it generally will not fit into the active site. Incorrect bases can be rejected before the phosphodiester bond is formed. The accuracy of the polymerization reaction itself, however, is insufficient to account for the high degree of fidelity in replication. Careful measurements in vitro have shown that DNA polymerases insert one incorrect nucleotide for every 10^4 to 10^6 correct ones. These mistakes sometimes occur because a base is briefly in an unusual tautomeric form (see Fig. 8-9), allowing it to hydrogenbond with an incorrect partner. In vivo, the error rate is reduced by additional enzymatic mechanisms. One mechanism intrinsic to virtually all DNA polymerases is a separate 3'—5' exonuclease activity that (a) Correct base pairs (b) Incorrect base pairs Active site shape GH o 25.1 DNA Replication 1015 double-checks each nucleotide after it is added. This nuclease activity permits the enzyme to remove a newly added nucleotide and is highly specific for mismatched base pairs (Fig. 25-7). If the polymerase has added the wrong nucleotide, translocation of the enzyme to the position where the next nucleotide is to be added is inhibited. This kinetic pause provides the opportunity for a correction. The 3'—>5' exonuclease activity removes the mispaired nucleotide, and the polymerase begins again. This activity, known as proofreading, is not simply the reverse of the polymerization reaction (Eqn 25-1), because pyrophosphate is not involved. The polymerizing and proofreading activities of a DNA polymerase can be measured separately. Proofreading improves the inherent accuracy of the polymerization reaction 10^4 - to 10^6 -fold. In the monomeric DNA polymerase I, the polymerizing and proofreading activities have separate active sites within the same polypeptide.

When base selection and proofreading are combined, DNA polymerase leaves behind one net error for every 10^9 to 10^{10} bases added. Yet the measured accuracy of replication in *E. coli* is higher still. The additional accuracy is provided by a separate enzyme system that repairs the mismatched base pairs remaining after replication. We describe this mismatch repair, along with other DNA repair processes, in Section 25.2. FIGURE 25-6 Contribution of base-pair geometry to the fidelity of DNA replication. (a) The standard A = T and G = C base pairs have very similar geometries, and an active site sized to fit one will generally accommodate the other. (b) The geometry of incorrectly paired bases can exclude them from the active site, as occurs on DNA polymerase.

1016 DNA Metabolism Polymerase mispairs dC with dT. bil (2) Polymerase repositions the mispaired 3' terminus into the 3'→5' exonuclease site. Exonuclease Postinsertion Insertion site site © Exonuclease hydrolyzes the mispaired dC. 3! The 3' terminus repositions back to the polymerase site. O Polymerase incorporates the correct nucleotide, dA. dATP FIGURE 25-7 An example of error correction by the 3'→5' exonuclease activity of DNA polymerase I. Structural analysis has located the exonuclease activity behind the polymerase activity as the enzyme is oriented in its movement along the DNA. A mismatched base (here, a C-T mismatch) impedes translocation of DNA polymerase | to the next site. The DNA bound to the enzyme slides backward into the exonuclease site, and the enzyme corrects the mistake with its 3'5' exonuclease activity. The enzyme then resumes its polymerase activity in the 5'—3' direction.

E. coli Has at Least Five DNA Polymerases More than 90% of the DNA polymerase activity observed in E. coli extracts can be accounted for by DNA polymerase I. Soon after the isolation of this enzyme in 1955, however, evidence began to accumulate that it is not suited for replication of the large E. coli chromosome. First, the rate at which it adds nucleotides (600 nucleotides/min) is too slow (by a factor of 100 or more) to account for the rates at which the replication fork moves in the bacterial cell. Second, DNA polymerase I has a relatively low processivity. Third, genetic studies have demonstrated that many genes, and therefore many proteins, are involved in replication: DNA polymerase I clearly does not act alone. Fourth, and most important, in 1969 John Cairns isolated a bacterial strain with an altered gene for DNA polymerase I that produced an inactive enzyme. Although this strain was abnormally sensitive to agents that damaged DNA, it was nevertheless viable! A search for other DNA polymerases led to the discovery of E. coli DNA polymerase II and DNA polymerase III in the early 1970s. DNA polymerase II is an enzyme involved in one type of DNA repair (Section 25.3). DNA polymerase III is the principal replication enzyme in E. coli. The properties of these three DNA polymerases are compared in Table 25-1. DNA polymerases IV and V, identified in 1999, are involved in an unusual form of DNA repair (Section 25.2).

Note that dnaE is an earlier designation for the gene now referred to as pol C. 'Polymerization subunit only. DNA polymerase II shares several subunits with DNA polymerase III, including the B, γ , δ , ϵ , θ , and W subunits (see Table 25-2).

DNA polymerase I, then, is not the primary enzyme of replication; instead it performs a host of cleanup functions during replication, recombination, and repair. The polymerase's special functions are enhanced by its 5'—3' exonuclease activity. This activity, distinct from the 3'—5' proofreading exonuclease (Fig. 25-7), is located in a structural domain that can be separated from the enzyme by mild protease treatment. When the 5'—3' exonuclease domain is removed, the remaining fragment (M_r 68,000), the large fragment or Klenow fragment, retains the polymerization and proofreading activities. The 5'—3' exonuclease activity of intact DNA polymerase I can replace a segment of DNA (or RNA) paired to the template strand, in a process known as nick translation (Fig. 25-8). Most other DNA polymerases lack a 5'—> 3' exonuclease activity. DNA polymerase III is much more complex than DNA polymerase I (Table 25-2). Its polymerization and proofreading activities reside in its α and ϵ (epsilon) subunits, respectively. The θ subunit associates with α and ϵ to form a core polymerase, which can polymerize DNA but with limited processivity. Two core polymerases can be linked by another set of subunits, a clamp-loading complex, or γ complex, consisting of five subunits of four different types, T2y66'. The core polymerases are linked through the τ (tau) subunits. τ 3'5' 5'3'3' exonuclease exonuclease 5' 3' Nucleic acid Nick to be removed | Postinsertion' Insertion site site NMPs or dNMPs released ϵ t dNTPs added # = A and PP; released 5' I 3 Pol | movement dNTPs

25.1 DNA Replication

1017 Two additional subunits, χ (chi) and ψ (psi), are bound to the clamp-loading complex. The entire assembly of 13 protein subunits (nine different types) is called DNA polymerase III* (Fig. 25-9a). DNA polymerase III* can polymerize DNA, but with a much lower processivity than one would expect for the organized replication of an entire chromosome. The necessary increase in processivity is provided by the addition of the β subunits, four of which complete the DNA polymerase III holoenzyme. The 8 subunits associate in pairs to form donut-shaped structures that encircle the DNA and act like clamps (Fig. 25-9b). Each dimer associates with a core subassembly of polymerase III* (one dimeric clamp per core subassembly) and slides along the DNA as replication proceeds. The β sliding clamp prevents the dissociation of DNA polymerase III from DNA, dramatically increasing processivity—to greater than

500,000 (Table 25-1). DNA Replication Requires Many Enzymes and Protein Factors Replication in *E. coli* requires not just a single DNA polymerase but 20 or more different enzymes and proteins, each performing a specific task. The entire complex has been termed the DNA replicase system or replisome. The enzymatic complexity of replication reflects the constraints imposed by the structure of DNA and by the requirements for accuracy. The main classes of replication enzymes are considered here in terms of the problems they overcome. Access to the DNA strands that are to act as templates requires separation of the two parent strands. This is generally accomplished by helicases, enzymes that move along the DNA and separate the strands, using chemical energy from ATP. Strand separation creates topological stress in the helical DNA structure (see Fig. 24-11), which is relieved by the action of topoisomerases. The separated strands are stabilized by DNA-binding proteins. As noted earlier, before DNA polymerases can begin synthesizing DNA, primers must be present on the template—generally, short RNA primers. The bacterial DNA polymerase III has three domains, catalyzing its DNA polymerase, 5'→3' exonuclease, and 3'→5' exonuclease activities. The 5'→3' exonuclease domain is in front of the enzyme as it moves along the DNA and is not shown in Figure 25-5. By degrading the DNA strand ahead of the enzyme and synthesizing a new strand behind, DNA polymerase III can promote a reaction called nick translation, where a break or nick in the DNA is effectively moved along with the enzyme. This process has a role in DNA repair and in the removal of RNA primers during replication (both described later). The strand of nucleic acid to be removed (either DNA or RNA) is shown in purple, the replacement strand in red. DNA synthesis begins at a nick (a broken phosphodiester bond, leaving a free 3' hydroxyl and a free 5' phosphate). A nick remains where DNA polymerase III eventually dissociates, and the nick is later sealed by another enzyme.

1018 | TABLE 25-2 | Subunits of DNA Polymerase III of *E. coli*

Subunit	Gene	Function	Number of subunits per holoenzyme

χ	dnaN	DNA clamp required for optimal processivity	1

*The γ subunit is encoded by a portion of the gene for the δ' subunit, such that the amino-terminal 66% of the δ' subunit has the same amino acid sequence as the γ subunit. The γ subunit is generated by a translational frameshifting mechanism (p. 1111) that leads to premature translational termination. segments of RNA synthesized by enzymes known as primases. Ultimately, the RNA primers are removed and replaced by DNA; in *E. coli*, this is one of the many functions of DNA polymerase I. After an RNA primer is removed and the gap is filled in with DNA, a nick (a broken phosphodiester bond) remains in the DNA backbone in the form of a broken phosphodiester bond. These nicks are sealed by DNA ligases. All these processes require coordination and regulation, an interplay best characterized in the *E. coli* system.

FIGURE 25-9 DNA polymerase III. (a) Architecture of bacterial DNA polymerase III (Pol III). Two core domains, composed of subunits α, ε, and θ, are linked by a five-subunit clamp-loading complex (also known as the γ complex) with the composition γ₂ψ₆χ₁. The core subunits and clamp-loader complex constitute DNA polymerase III*. The γ and δ' subunits are encoded by the same gene. The γ subunit is a shortened version of the δ' subunit; γ thus contains a domain identical to δ', along with an additional segment that interacts with the core polymerase. The other two subunits of DNA polymerase III*, χ and θ (not shown), also bind to the clamp-loading complex. Two β clamps interact each clamp a dimer of the β subunit with the two-core subassembly, nit. The complex interacts with the DnaB helicase (described later in the text) through the δ' subunits. (b) Two β subunits of *E. coli* polymerase III form a circular clamp that

surrounds the DNA. The clamp slides along the DNA molecule, increasing the processivity of the polymerase III holoenzyme to greater than 500,000 nucleotides from the DNA. The two β subunits by preventing its dissociation are shown in two shades of purple as ribbon structures (left) and surface images (right), surrounding the DNA (derived from PDB ID 2POL).

The horizontal arrows indicate the orientations of the nucleotide sequences (left-to-right arrow denotes Replication of the *E. coli* Chromosome Proceeds in Stages The synthesis of a DNA molecule can be divided into three stages: initiation, elongation, and termination, distinguished both by the reactions taking place and by the enzymes required. As you will find here and in the next two chapters, synthesis of the major information-containing biological polymers—DNAs, RNAs, and proteins—can be understood in terms of these same three stages, with the stages of each pathway having unique characteristics. The events described below reflect information derived primarily from *in vitro* experiments using purified *E. coli* proteins, although the principles are highly conserved in all replication systems. Initiation The *E. coli* replication origin, *oriC*, consists of 245 bp and contains DNA sequence elements that are highly conserved among bacterial replication origins. The general arrangement of the conserved sequences is illustrated in Figure 25-10. Two types of sequences sequence in top strand; right-to-left, bottom strand). FIS and IHF are binding sites for proteins described in the text. R sites are bound by DnaA. | sites are additional DnaA-binding sites (with different sequences), bound by DnaA only when the protein is complexed with ATP. are of special interest: five repeats of a 9 bp sequence (R sites) that serve as binding sites for the key initiator protein DnaA, and a region rich in A = T base pairs called the DNA unwinding element (DUE). There are three additional DnaA-binding sites (1 sites), and binding sites for the proteins IHF (integration host factor) and FIS (factor for inversion stimulation). These two proteins were discovered as required components of certain recombination reactions described later in this chapter, and their names reflect those roles. Another DNA-binding protein, HU (a histonelike bacterial protein originally dubbed factor U), also participates but does not have a specific binding site. At least 10

different enzymes or proteins (summarized in Table 25-3) participate in the initiation phase of replication. They open the DNA helix at the origin and establish a prepriming complex for subsequent reactions. The crucial component in the initiation process is the DnaA protein, a member of the AAA + ATPase protein family (ATPases associated with diverse cellular activities). Many AAA + ATPases, including DnaA, | TABLE 25-3 | Proteins Required to Initiate Replication at the E. coli Origin

1020 DNA Metabolism DnaA-ATP ge — Š Origin binding i

FIGURE 25-11 Model for initiation of replication at the *E. coli* origin, *oriC*. Eight DnaA protein molecules, each with a bound ATP, bind at the R and I sites in the origin (see Fig. 25-10). The DNA is wrapped around this complex, forming a right-handed helical structure. The A = T-rich DUE region is denatured as a result of the strain imparted by the adjacent DnaA binding. DnaA forms oligomers and hydrolyze ATP relatively slowly. This ATP hydrolysis acts as a switch mediating interconversion of the protein between two states. In the case of DnaA, the ATP-bound form is active and the ADP-bound form is inactive. Eight DnaA protein molecules, all in the ATP-bound state, assemble to form a helical complex encompassing the R and I sites in *oriC* (Fig. 25-11). DnaA has a higher affinity for the R sites than I sites, and binds R sites equally well in its ATP- or ADP-bound form. The I sites, which bind only the ATP-bound DnaA, allow discrimination between the active and inactive forms of DnaA. The tight right-handed wrapping of the DNA around this complex introduces an effective positive supercoil (see Chapter 24). The associated strain in the nearby DNA leads to denaturation in the A = T-rich DUE region. The complex formed at the replication origin also includes several DNA-binding proteins—HU, IHF, and FIS—that facilitate DNA bending. The DnaC protein, another AAA + ATPase, then loads the DnaB protein onto the separated DNA strands in the denatured region. A hexamer of DnaC, each subunit bound to ATP, forms a tight complex with the hexameric, ring-shaped DnaB helicase. This DnaC-DnaB interaction opens the DnaB ring, the process being aided by a further interaction between DnaB and DnaA. Two of the ring-shaped DnaB hexamers are loaded in the DUE, one onto each DNA strand. The ATP bound to DnaC is hydrolyzed, releasing the DnaC and leaving the DnaB bound to the DNA. Loading of the DnaB helicase is the key step in replication initiation. As a replicative helicase, DnaB migrates along the single-stranded DNA in the 5' → 3' direction, unwinding the DNA as it travels. The DnaB helicases loaded onto the two DNA strands thus travel in opposite directions, creating two potential replication forks. All other proteins at the replication fork are linked directly or indirectly to DnaB. The DNA polymerase III | DnaA-dependent denaturation of the DUE region DnaC-dependent loading of DnaB DnaB helicase w DnaC-ATP $\rightarrow$ DnaC + ADP + P;

Formation of the helical DnaA complex is facilitated by the proteins HU, IHF, and FIS, which are not shown here because their detailed structural roles have not yet been defined. Hexamers of the DnaB protein bind to each strand, with the aid of DnaC protein. The DnaB helicase activity further unwinds the DNA in preparation for priming and DNA synthesis. holoenzyme is linked through the 7 subunits; additional DnaB interactions are described below. As replication begins and the DNA strands are separated at the fork, many molecules of single-stranded DNA-binding protein (SSB) bind to and stabilize the separated strands, and DNA gyrase (DNA topoisomerase II) relieves the topological stress induced ahead of the fork by the unwinding reaction. Initiation is the only phase of DNA replication that is known to be regulated, and it is regulated such that replication occurs only once in each cell cycle. The mechanism of regulation is not yet entirely understood, but genetic and biochemical studies have provided insights into several separate regulatory mechanisms. Once DNA polymerase III has been loaded onto the DNA, along with the 8 subunits (signaling completion of the initiation phase), the protein Hda binds to the B subunits and interacts with DnaA to stimulate hydrolysis of its bound ATP. Hda is yet another AAA + ATPase closely related to DnaA (its name is derived from homologous to DnaA). This ATP hydrolysis leads to disassembly of the DnaA complex at the origin. Slow release of ADP by DnaA and rebinding of ATP cycles the protein between its inactive (with bound ADP) and active (with bound ATP) forms on a time scale of 20 to 40 minutes. The timing of replication initiation is affected by DNA methylation and interactions with the bacterial plasma membrane. The *oriC* DNA is methylated by the Dam methylase (Table 25-3), which methylates the N^o position of adenine within the palindromic sequence (5')GATC. (Dam is not a biochemical expletive; it stands for DNA adenine methylation.) The *oriC* region of *E. coli* is highly enriched in GATC sequences—it has 11 of them in its 245 bp, whereas the average frequency of GATC in the *E. coli* chromosome as a whole is 1 in 256 bp. Immediately after replication, the DNA is hemimethylated: the parent strands have methylated *oriC* sequences

but the newly synthesized strands do not. The hemimethylated *oriC* sequences are now sequestered by interaction with the plasma membrane (the mechanism is unknown) and by binding of the protein SeqA. After a time, *oriC* is released from the plasma membrane, SeqA dissociates, and the DNA must be fully methylated by Dam methylase before it can again bind DnaA and initiate a new round of replication.

Elongation The elongation phase of replication includes two distinct but related operations: leading strand synthesis and lagging strand synthesis. Several enzymes at the replication fork are important to the synthesis of both strands. Parent DNA is first unwound by DNA helicases, and the resulting topological stress is relieved by topoisomerases. Each separated strand is then stabilized by SSB. From this point, synthesis of leading and lagging strands is sharply different. Leading strand synthesis, the more straightforward of the two, begins with the synthesis by primase (DnaG protein) of a short (10 to 60 nucleotide) RNA primer at the replication origin. DnaG interacts with DnaB helicase to carry out this reaction, and the primer is synthesized in the direction opposite to that in which the DnaB helicase is moving. In effect, the DnaB helicase moves along the strand that becomes the lagging strand in DNA synthesis; however, the first DNA topoisomerase II (DNA gyrase) @) REDENS fork movement DnaB helicase Primase SSB RNA primer ar La 25.1 DNA Replication 1021 primer laid down in the first DnaG-DnaB interaction serves to prime leading strand DNA synthesis in the opposite direction. Deoxyribonucleotides are added to this primer by a DNA polymerase III complex linked to the DnaB helicase tethered to the opposite DNA strand. Leading strand synthesis then proceeds continuously, keeping pace with the unwinding of DNA at the replication fork. Lagging strand synthesis, as we have noted, is accomplished in short Okazaki fragments (Fig. 25-12a). First, an RNA primer is synthesized by primase and, as in leading strand synthesis, DNA polymerase III binds to the RNA primer and adds deoxyribonucleotides (Fig. 25-12b). On this level, the synthesis of each Okazaki fragment seems straightforward, but the reality is quite complex. The complexity lies in the coordination of leading and lagging strand synthesis. Both strands are produced by a single asymmetric DNA polymerase III dimer; this is accomplished by looping the DNA of the lagging strand as shown in Figure 25-13,

bringing together the two points of polymerization. The synthesis of Okazaki fragments on the lagging strand entails some elegant enzymatic choreography. DnaB helicase and DnaG primase constitute a functional unit within the replication complex, the primosome. DNA polymerase III uses one set of its core Leading strand synthesis (DNA polymerase III) Lagging strand 5' RNA primer from previous Okazaki fragment (b) ———™ Lagging strand synthesis (DNA polymerase III) FIGURE 25-12 Synthesis of Okazaki fragments. (a) At intervals, primase synthesizes an RNA primer for a new Okazaki fragment. Note that if we consider the two template strands as lying side by side, lagging strand synthesis formally proceeds in the opposite direction from fork movement. (b) Each primer is extended by DNA polymerase III. (c) DNA synthesis continues until the fragment extends as far as the primer of the previously added Okazaki fragment. A new primer is synthesized near the replication fork to begin the process again.

1022 DNA Metabolism (a) Continuous synthesis Core on the leading strand i E in proceeds as DNA is strand DnaB helicase. unwound by the Clamp-loading complex with open £ sliding clamp € _ Lagging strand ' RNA primer of previous Okazaki fragment Primase w (b) Okazaki fragment synthesis nears completion. Primase Primase binds to DnaB, synthesizes a new primer, then dissociates. (c) A new £ clamp is loaded onto the new template primer by the clamp loader. 4 eSynthesis of a new Okazaki fragment is completed on the lagging strand. subunits (the core polymerase) to synthesize the leading strand continuously, while the other set of core subunits cycles from one Okazaki fragment to the next on the looped lagging strand. DnaB helicase, bound in front of DNA polymerase II, unwinds the DNA at the replication fork (Fig. 25-13a) as it travels along the lagging strand template in the 5'—3' direction. DnaG primase occasionally associates with DnaB helicase and synthesizes a short RNA primer (Fig. 25-13b). A new £ sliding clamp is then positioned at the primer by the clamp-loading complex of DNA FIGURE 25-13 DNA synthesis on the leading and lagging strands. Events at the replication fork are coordinated by a single DNA polymerase III dimer, in an integrated complex with DnaB helicase. This figure shows the replication process already underway (parts (a) through (e) are discussed in the text). The lagging strand is looped so that DNA synthesis proceeds steadily on both the leading and lagging strand templates at the same time. Red arrows indicate the 3' end of the two new strands and the direction of DNA synthesis. The heavy black arrows show the direction of movement of the parent DNA through the complex. An Okazaki fragment is being synthesized on the lagging strand. The subunit colors and the functions of the clamp-loading complex are explained in Figure 25-14. é DNA Synthesis (e) The next 6 clamp is readied as Okazaki fragment synthesis is initiated. Lagging strand core subunits are transferred to the new template primer and its 6 clamp. The old B clamp is left behind. (d) B clamp left behind polymerase III (Fig. 25-13c). When synthesis of an Okazaki fragment has been completed, replication halts, and the core subunits of DNA polymerase III dissociate from their B sliding clamp (and from the completed Okazaki fragment) and associate with the new clamp (Fig. 25—13d, e). This initiates synthesis of a new Okazaki fragment. As noted earlier, the entire complex

responsible for coordinated DNA synthesis at a replication fork is known as the replisome. The proteins acting at the replication fork are summarized in Table 25-4.

Clamp loader \ B clamp

ATP A $\text{ATP} \rightarrow \text{Alp} + \text{J} + 3' \text{ADP}$

The clamp-loading complex of DNA polymerase II, consisting of parts of the two γ , δ , and δ' subunits, is also an AAA + ATPase. This complex binds to ATP and to the new β sliding clamp. The binding imparts strain on the dimeric clamp, opening up the ring at one subunit interface (Fig. 25-14). The newly primed lagging strand is slipped into the ring through the resulting break. The clamp loader then hydrolyzes ATP, releasing the β sliding clamp and allowing it to close around the DNA. The replisome promotes rapid DNA synthesis, adding $\sim 1,000$ nucleotides/s to each strand (leading and lagging). Once an Okazaki fragment has been completed, its RNA primer is removed and replaced with DNA by DNA polymerase I, and the remaining nick is sealed by DNA ligase (Fig. 25-15). DNA ligase catalyzes the formation of a phosphodiester bond between a 3' hydroxyl at the end of one DNA strand and a 5' phosphate at the end of another strand. The phosphate must be activated by adenylation. DNA ligases isolated from viruses and eukaryotes use ATP for this purpose. DNA ligases from bacteria are unusual in that many use NAD^+ —a cofactor that usually functions in hydride transfer reactions (see Fig. 13-24)—as the source of the AMP activating group (Fig. 25-16). DNA ligase is another enzyme of DNA metabolism that has become an

FIGURE 25-14 The DNA polymerase III clamp loader. The five subunits of the clamp-loading complex are the γ , δ , and δ' subunits and the amino-terminal domain of each α subunit (see Fig. 25-9). The complex binds to three molecules of ATP and to a dimeric B clamp. This binding forces the B clamp open at one of its two subunit interfaces. Hydrolysis of the bound ATP allows the B clamp to close again

In each of the three steps, one phosphodiester bond is formed at the expense of another. Steps @ and @ lead to activation of the 5' phosphate in the nick. An AMP group is transferred first to a Lys residue on the enzyme and then to the 5' phosphate in the nick. In step ©, the 3'-hydroxyl containing multiple copies of a 20 bp sequence called Ter (Fig. 25-17). The Ter sequences are arranged on the chromosome to create a trap that a replication fork Origin see RY fork TerB TerC TerA Counterclockwise fork trap Clockwise fork trap FIGURE 25-17 Termination of chromosome replication in *E. coli*. The Ter sequences (TerA through TerJ) are positioned on the chromosome in two clusters with opposite orientations. group attacks this phosphate and displaces AMP, producing a phosphodiester bond to seal the nick. In the *E. coli* DNA ligase reaction, AMP is derived from NAD*. The DNA ligases isolated from some viral and eukaryotic sources use ATP rather than NAD* and they release pyrophosphate rather than nicotinamide mononucleotide (NMN) in step @. can enter but cannot leave. The Ter sequences function as binding sites for the protein Tus (terminus utilization substance). The Tus-Ter complex can arrest a replication fork from only one direction. Only one Tus-Ter complex functions per replication cycle—the complex first encountered by either replication fork. Given that opposing replication forks generally halt when they collide, Ter sequences would not seem to be essential, but they may prevent overreplication by one fork in the event that the other is delayed or halted by an encounter with DNA damage or some other obstacle. So, when either replication fork encounters a functional Tus-Ter complex, it halts; the other fork halts when it meets the first (arrested) fork. The final few hundred base pairs of DNA between these large protein complexes are then replicated (by an as yet unknown mechanism), completing two topologically interlinked

(catenated) circular chromosomes (Fig. 25-18). DNA circles linked in this way are known as catenanes. Separation of the catenated circles in *E. coli* requires

Counterclockwise fork completion of replication Catenated chromosomes DNA topoisomerase IV Separated chromosomes

FIGURE 25-18 Role of topoisomerases in replication termination. Replication of the DNA separating opposing replication forks leaves the completed chromosomes joined as catenanes, or topologically interlinked circles. The circles are not covalently linked, but because they are interwound and each is covalently closed, they cannot be separated— except by the action of topoisomerases. In *E. coli*, a type II topoisomerase known as DNA topoisomerase IV plays the primary role in the separation of catenated chromosomes, transiently breaking both DNA strands of one chromosome and allowing the other chromosome to pass through the break. topoisomerase IV (a type II topoisomerase). The separated chromosomes then segregate into daughter cells at cell division. The terminal phase of replication of other circular chromosomes, including many of the DNA viruses that infect eukaryotic cells, is similar.

Replication in Eukaryotic Cells Is Similar but More Complex The DNA molecules in eukaryotic cells are considerably larger than those in bacteria and are organized into complex nucleoprotein structures (chromatin; p. 994). The essential features of DNA replication are the same 25.1 DNA Replication 1025 in eukaryotes and bacteria, and many of the protein complexes are functionally and structurally conserved. However, eukaryotic replication is regulated and coordinated with the cell cycle, introducing some additional complexities. Origins of replication have a well-characterized structure in some lower eukaryotes, but they are much less defined in higher eukaryotes. In vertebrates, a variety of A = T-rich sequences may be used for replication initiation, and the sites may vary from one cell division to the next. Yeast (*Saccharomyces cerevisiae*) has defined replication origins called autonomously replicating sequences (ARS), or replicators. Yeast replicators span ~150 bp and contain several essential, conserved sequences. About 400 replicators are distributed among the 16 chromosomes of the haploid yeast genome. Regulation ensures that all cellular DNA is replicated once per cell cycle. Much of this regulation involves proteins called cyclins and the cyclin-dependent kinases (CDKs) with which they form complexes (p. 484). The cyclins are rapidly destroyed by ubiquitin-dependent proteolysis at the end of the M phase (mitosis), and the absence of cyclins allows

the establishment of prereplicative complexes (pre-RCs) on replication initiation sites. In rapidly growing cells, the pre-RC forms at the end of M phase. In slow-growing cells, it does not form until the end of G1. Formation of the pre-RC renders the cell competent for replication, an event sometimes called licensing. As in bacteria, the key event in the initiation of replication in all eukaryotes is the loading of the replicative helicase, a heterohexameric complex of minichromosome maintenance (MCM) proteins (MCM2 to MCM7). The ring-shaped MCM2-7 helicase, functioning much like the bacterial DnaB helicase, is loaded onto the DNA by another six-protein complex called ORC (origin recognition complex) (Fig. 25-19). ORC has five AAA + ATPase domains among its subunits and is functionally analogous to the bacterial DnaA. Two other proteins, CDC6 (cell division cycle) and CDT1 (CDC10-dependent transcript /), are also required to load the MCM2-7 complex, and the yeast CDC6 is another AAA + ATPase. Commitment to replication requires the synthesis and activity of S-phase cyclin-CDK complexes (such as the cyclin E-CDK2 complex; see Fig. 12-46) and CDC7DBF4. Both types of complexes help to activate replication by binding to and phosphorylating several proteins in the pre-RC. Other cyclins and CDKs function to inhibit the formation of more pre-RC complexes once replication has been initiated. For example, CDK2 binds to cyclin A as cyclin E levels decline during S phase, inhibiting CDK2 and preventing the licensing of additional pre-RC complexes. The rate of movement of the replication fork in eukaryotes (~ 50 nucleotides/s) is only one-twentieth that observed in *E. coli*. At this rate, replication of an

FIGURE 25-19 Assembly of a pre-replicative complex at a eukaryotic replication origin. The initiation site (origin) is bound by ORC, CDC6, and CDT1. These proteins, many of them AAA + ATPases, promote loading of the replicative helicase, MCM2-7, in a reaction that is analogous to the loading of the bacterial DnaB helicase by DnaC protein. Loading of the MCM helicase complex onto the DNA forms the prereplicative complex, or pre-RC, and is the key step in the initiation of replication. average human chromosome proceeding from a single origin would take more than 500 hours. Replication of human chromosomes in fact proceeds bidirectionally from many origins, spaced 30 to 300 kbp apart. Eukaryotic chromosomes are almost always much larger than bacterial chromosomes, so multiple origins are probably a universal feature of eukaryotic cells. Like bacteria, eukaryotes have several types of DNA polymerases. Some have been linked to particular functions, such as the replication of mitochondrial DNA. The replication of nuclear chromosomes involves DNA polymerase α , in association with DNA polymerase δ . DNA polymerase α is typically a multisubunit enzyme with similar structure and properties in all eukaryotic cells. One subunit has a primase activity, and the largest subunit (M, $\sim 180,000$) contains the polymerization activity. However, this polymerase has no proofreading 3'—5' exonuclease activity, making it unsuitable for high-fidelity DNA replication. DNA polymerase α is believed to function only in the synthesis of short primers (either RNA or DNA) for Okazaki fragments on the lagging strand. These primers are then extended by the multisubunit DNA polymerase δ . This enzyme is associated with and stimulated by proliferating cell nuclear antigen (PCNA; M, 29,000), a protein found in large amounts in the nuclei of proliferating cells. The three-dimensional structure of PCNA is remarkably similar to that of the B subunit of *E. coli* DNA polymerase III (Fig. 25-9b), although primary sequence homology is not evident. PCNA has a function analogous to that of the B subunit, forming a circular clamp that greatly enhances the processivity of the polymerase. DNA polymerase δ has a 3'—5' proofreading exonuclease activity and seems to carry out both leading and lagging strand synthesis in a complex comparable to the dimeric bacterial DNA polymerase III. Yet another polymerase, DNA polymerase ϵ , replaces DNA

polymerase δ in some situations, such as in DNA repair. DNA polymerase ϵ may also function at the replication fork, perhaps playing a role analogous to that of the bacterial DNA polymerase I, removing the primers of Okazaki fragments on the lagging strand. Two other protein complexes also function in eukaryotic DNA replication. RPA (replication protein A) is a eukaryotic single-stranded DNA-binding protein, equivalent in function to the *E. coli* SSB protein. RFC (replication factor C) is a clamp loader for PCNA and facilitates the assembly of active replication complexes. The subunits of the RFC complex have significant sequence similarity to the subunits of the bacterial clamp-loading (γ) complex. The termination of replication on linear eukaryotic chromosomes involves the synthesis of special structures called telomeres at the ends of each chromosome, as discussed in the next chapter.

Viral DNA Polymerases Provide Targets for Antiviral Therapy

Many DNA viruses encode their own DNA polymerases, and some of these have become targets for pharmaceuticals. For example, the DNA polymerase of the herpes simplex virus is inhibited by acyclovir, a compound developed by Gertrude Elion and

George Hitchings (p. 923). Acyclovir consists of guanine attached to an incomplete ribose ring. O N O) HN "N~ N O L Se Acyclovir It is phosphorylated by a virally encoded thymidine kinase; acyclovir binds to this viral enzyme with an affinity 200-fold greater than its binding to the cellular thymidine kinase. This ensures that phosphorylation occurs mainly in virus-infected cells. Cellular kinases convert the resulting acyclo-GMP to acyclo-GTP, which is both an inhibitor and a substrate of DNA polymerases; acyclo-GTP competitively inhibits the herpes DNA polymerase more strongly than cellular DNA polymerases. Because it lacks a 3' hydroxyl, acyclo-GTP also acts as a chain terminator when incorporated into DNA. Thus viral replication is inhibited at several steps.

E SUMMARY 25.1 DNA Replication > Replication of DNA occurs with very high fidelity and at a designated time in the cell cycle. Replication is semiconservative, each strand acting as template for a new daughter strand. It is carried out in three identifiable phases: initiation, elongation, and termination. The process starts at a single origin in bacteria and usually proceeds bidirectionally. > DNA is synthesized in the 5'-3' direction by DNA polymerases. At the replication fork, the leading strand is synthesized continuously in the same direction as replication fork movement; the lagging strand is synthesized discontinuously as Okazaki fragments, which are subsequently ligated. > The fidelity of DNA replication is maintained by (1) base selection by the polymerase, (2) a 3'—5' proofreading exonuclease activity that is part of most DNA polymerases, and (3) specific repair systems for mismatches left behind after replication. > Most cells have several DNA polymerases. In *E. coli*, DNA polymerase III is the primary replication enzyme. DNA polymerase I is responsible for special functions during replication, recombination, and repair. > The separate initiation, elongation, and termination phases of DNA replication involve an array of enzymes and protein factors, many belonging to the AAA + ATPase family.

25.2 DNA Repair 1027 > The major replicative DNA polymerase in eukaryotes is DNA polymerase δ . DNA polymerase α functions to synthesize primers. DNA polymerase ϵ functions in DNA repair.

25.2 DNA Repair Most cells have only one or two sets of genomic DNA. Damaged proteins and RNA molecules can be quickly replaced by using information encoded in the DNA, but DNA molecules themselves are

irreplaceable. Maintaining the integrity of the information in DNA is a cellular imperative, supported by an elaborate set of DNA repair systems. DNA can become damaged by a variety of processes, some spontaneous, others catalyzed by environmental agents (Chapter 8). Replication itself can very occasionally damage the information content in DNA when errors introduce mismatched base pairs (such as G paired with T). The chemistry of DNA damage is diverse and complex. The cellular response to this damage includes a wide range of enzymatic systems that catalyze some of the most interesting chemical transformations in DNA metabolism. We first examine the effects of alterations in DNA sequence and then consider specific repair systems.

Mutations Are Linked to Cancer

The best way to illustrate the importance of DNA repair is to consider the effects of unrepaired DNA damage (a lesion). The most serious outcome is a change in the base sequence of the DNA, which, if replicated and transmitted to future generations of cells, becomes permanent. A permanent change in the nucleotide sequence of DNA is called a mutation. Mutations can involve the replacement of one base pair with another (substitution mutation) or the addition or deletion of one or more base pairs (insertion or deletion mutations). If the mutation affects nonessential DNA or if it has a negligible effect on the function of a gene, it is known as a silent mutation. Rarely, a mutation confers some biological advantage. Most nonsilent mutations, however, are neutral or deleterious. In mammals there is a strong correlation between the accumulation of mutations and cancer. A simple test developed by Bruce Ames measures the potential of a given chemical compound to promote certain easily detected mutations in a specialized bacterial strain (Fig. 25-20). Few of the chemicals that we encounter in daily life score as mutagens in this test. However, of the compounds known to be carcinogenic from extensive animal trials, more than 90% are also found to be mutagenic in the Ames test. Because of this strong correlation between mutagenesis and carcinogenesis, the Ames test for bacterial mutagens is widely used as a

1028 DNA Metabolism FIGURE 25-20 Ames test for carcinogens, based on their mutagenicity. A strain of *Salmonella typhimurium* having a mutation that inactivates an enzyme of the histidine biosynthetic pathway is plated on a histidine-free medium. Few cells grow. (a) The few small colonies of *S. typhimurium* that do grow on a histidine-free medium carry spontaneous backmutations that permit the histidine biosynthetic pathway to operate. Three identical nutrient plates (b), (c), and (d) have been inoculated with an equal number of cells. Each plate then receives a disk of filter paper containing progressively lower concentrations of a mutagen. The mutagen greatly increases the rate of back-mutation and hence the number of colonies. The clear areas around the filter paper indicate where the concentration of mutagen is so high that it is lethal to the cells. As the mutagen diffuses away from the filter paper, it is diluted to sublethal concentrations that promote back-mutation. Mutagens can be compared on the basis of their effect on mutation rate. Because many compounds undergo a variety of chemical transformations after entering cells, compounds are sometimes tested for mutagenicity after first incubating them with a liver extract. Some substances have been found to be mutagenic only after this treatment. rapid and inexpensive screen for potential human carcinogens. The genomic DNA in a typical mammalian cell accumulates many thousands of lesions during a 24-hour period. However, as a result of DNA repair, fewer than 1 in 1,000 become a mutation. DNA is a relatively stable molecule, but in the absence of repair systems, the cumulative effect of many infrequent but damaging reactions would make life impossible. E All Cells Have Multiple DNA Repair Systems The number and diversity of repair systems reflect both the importance of DNA repair to cell survival and the diverse sources of DNA damage (Table 25-5). Some common types of lesions, such as pyrimidine dimers (see Fig. 8-31), can be repaired by several distinct | TABLE 25-5 | Types of DNA Repair Systems in *E. coli* Enzymes/proteins Type of damage Mismatch repair Dam methylase MutH, MutL, MutS proteins DNA helicase II SSB DNA polymerase III Exonuclease I Exonuclease VII RecJ nuclease Exonuclease X DNA ligase Base-excision repair Mismatches Abnormal bases (uracil, hypoxanthine, xanthine); alkylated bases; in some other organisms, pyrimidine dimers DNA glycosylases AP endonucleases DNA polymerase I DNA ligase

Many DNA repair processes also seem to be extraordinarily inefficient energetically—an exception to the pattern observed in the vast majority of metabolic pathways, where every ATP is generally accounted for and used optimally. When the integrity of the genetic information is at stake, the amount of chemical energy invested in a repair process seems almost irrelevant. DNA repair is possible largely because the DNA molecule consists of two complementary strands. DNA damage in one strand can be removed and accurately replaced by using the undamaged complementary strand as a template. We consider here the principal types of repair systems, beginning with those that repair the rare nucleotide mismatches that are left behind by replication. Mismatch Repair Correction of the rare mismatches left after replication in *E. coli* improves the overall fidelity

of replication by an additional factor of 10^6 to 10^8 . The mismatches are nearly always corrected to reflect the information in the old (template) strand, so the repair system must somehow discriminate between the template and the newly synthesized strand. The cell accomplishes this by tagging the template DNA with methyl groups to distinguish it from newly synthesized strands. The mismatch repair system of *E. coli* includes at least 12 protein components (Table 25-5) that function either in strand discrimination or in the repair process itself. The strand discrimination mechanism has not been worked out for most bacteria or eukaryotes, but is well understood for *E. coli* and some closely related bacterial species. In these bacteria, strand discrimination is based on the action of Dam methylase, which, as you will recall, methylates DNA at the N⁶ position of all adenines within (5')GATC sequences. Immediately after passage of the replication fork, there is a short period (a few seconds or minutes) during which the template strand is methylated but the newly synthesized strand is not (Fig. 25-21). The transient unmethylated state of GATC sequences in the newly synthesized strand permits the new strand to be distinguished from the template strand. Replication mismatches in the vicinity of a hemimethylated GATC sequence are then repaired according to the information in the methylated parent (template) strand. Tests in vitro show that if both strands are methylated at a GATC sequence, few mismatches are repaired; if neither strand is methylated, repair occurs but does not favor either strand. The cell's methyl-directed mismatch repair system efficiently repairs mismatches up to 1,000 bp from a hemimethylated GATC sequence. How is the mismatch correction process directed by relatively distant GATC sequences? A mechanism is illustrated in Figure 25-22. MutL protein forms a complex with MutS protein, and the complex binds to all mismatched base pairs (except C-C). MutH protein binds to MutL and to GATC sequences encountered by the MutL-MutS complex. DNA on both sides of the mismatch is threaded through the MutL-MutS complex, creating a DNA loop; simultaneous movement of both legs of the loop through the complex is equivalent to the complex moving in both directions at once along the DNA. MutH has a site-specific endonuclease activity that is inactive until the complex encounters a hemimethylated GATC sequence. At this site,

MutH FIGURE 25-21 Methylation and mismatch repair. Methylation of DNA strands can serve to distinguish parent (template) strands from newly synthesized strands in *E. coli* DNA, a function that is critical to mismatch repair (see Fig. 25-22). The methylation occurs at the N^ε of adenines in (5')GATC sequences. This sequence is a palindrome (see Fig. 8-18), present in opposite orientations on the two strands. 25.2 DNAREpair 1029 catalyzes cleavage of the unmethylated strand on the 5' side of the G in GATC, which marks the strand for repair. Further steps in the pathway depend on where
 lls > GATC " 7 CTAG k CH, replication For a short period following replication, the template strand is methylated and the new strand is not. After a few minutes the new strand is methylated and the two strands can no longer be distinguished. Dam methylase Sor ee ee r

ADP + P; MutL-MutS complex ATP. MutH ADP + P; MutH MutH
cleaves the unmethylated strand FIGURE 25-22 A model for the
early steps of methyl-directed mismatch repair. The proteins
involved in this process in *E. coli* have been purified (see Table
25-5). Recognition of the sequence (5')GATC and of the mismatch
are specialized functions of the MutH and MutS proteins,
respectively. The MutL protein forms a complex with MutS at the
mismatch. DNA is threaded through this complex such that the
complex moves simultaneously in both directions along the DNA
until it encounters a MutH protein bound at a hemimethylated GATC
sequence. MutH cleaves the unmethylated strand on the 5' side of
the G in this sequence. A complex consisting of DNA helicase II and
one of several exonucleases then degrades the unmethylated DNA
strand from that point toward the mismatch (see Fig. 25-23). The
mismatch is located relative to this cleavage site (Fig. 25-23). When
the mismatch is on the 5' side of the cleavage site (Fig. 25-23, right
side), the unmethylated strand is unwound and degraded in the 3'—
> 5' direction from the cleavage site through the mismatch, and this
segment is replaced with new DNA. This process requires the
combined action of DNA helicase II (also called UvrD helicase), SSB,
exonuclease I or exonuclease X (both of which degrade strands of
DNA in the 3'—> 5' direction), DNA polymerase III, and DNA ligase.
The pathway for repair of mismatches on the 3' side of the cleavage
site is similar (Fig. 25-23, left), except that the exonuclease is either
exonuclease VII (which degrades single-stranded DNA in the 5'—3'
or 3'—> 5' direction) or RecJ nuclease (which degrades single-
stranded DNA in the 5'—3' direction). Mismatch repair is a
particularly expensive process for *E. coli* in terms of energy
expended. The mismatch may be 1,000 bp or more from the GATC
sequence. The degradation and replacement of a strand segment of
this length require an enormous investment in activated
deoxynucleotide precursors to repair a single mismatched base. This
again underscores the importance to the cell of genomic integrity.
All eukaryotic cells have several proteins structurally and
functionally analogous to the bacterial MutS and MutL (but not
MutH) proteins. Alterations in human genes encoding proteins of
this type produce some of the most common inherited cancer-
susceptibility syndromes (see Box 25-1, p. 1037), further

demonstrating the value to the organism of DNA repair systems. The main MutS homologs in most eukaryotes, from yeast to humans, are MSH2 (MutS homolog), MSH3, and MSH6. Heterodimers of MSH2 and MSH6 generally bind to single base-pair mismatches, and bind less well to slightly longer mispaired loops. In many organisms the longer mismatches (2 to 6 bp) may be bound instead by a heterodimer of MSH2 and MSH3, or are bound by both types of heterodimers in tandem. Homologs of MutL, predominantly a heterodimer of MLH1 (MutL homolog) and PMS1 (post-meiotic segregation), bind to and stabilize the MSH complexes. Many details of the subsequent events in eukaryotic mismatch repair remain to be worked out. In particular, we do not know the mechanism by which newly synthesized DNA strands are identified, although research has revealed that this strand identification does not involve GATC sequences.

Base-Excision Repair Every cell has a class of enzymes called DNA glycosylases that recognize particularly common DNA lesions (such as the products of cytosine and adenine deamination; see Fig. 8-30a) and remove the affected base by cleaving the N-glycosyl bond. This cleavage creates an apurinic or apyrimidinic site in the DNA, commonly referred to as an AP site or abasic site. Each DNA glycosylase is generally specific for one type of lesion. Uracil DNA glycosylases, for example, found in most cells, specifically remove from DNA the uracil that results from spontaneous deamination of cytosine. Mutant cells that lack this enzyme have a high rate of G = C to A = T mutations. This glycosylase does not remove uracil residues from RNA or thymine residues from DNA. The capacity to distinguish thymine from uracil, the product of cytosine deamination—necessary for the selective repair of the latter—may be one reason

FIGURE 25-23 Completing methyl-directed mismatch repair. The combined action of DNA helicase II, SSB, and one of four different exonucleases removes a segment of the new strand between the MutH cleavage site and a point just beyond the mismatch. The exonuclease why DNA evolved to contain thymine instead of uracil (p. 299). Most bacteria have just one type of uracil DNA glycosylase, whereas humans have at least four types, with different specificities—an indicator of the importance of uracil removal from DNA. The most abundant human uracil glycosylase, UNG, is associated with the human replisome, where it eliminates the occasional U residue inserted in place of a T during replication. The deamination of C residues is 100-fold faster in single-stranded DNA than in double-stranded DNA, and humans have the enzyme hSMUG1, which removes any U residues that occur in single-stranded DNA during replication or transcription. Two other human DNA glycosylases, TDG and MBD4, remove either U or T residues paired with G, generated by deamination of cytosine or 5-methylcytosine, respectively. Other DNA glycosylases recognize and remove a variety of damaged bases, including formamidopyrimidine and 8-hydroxyguanine (both arising from purine oxidation), hypoxanthine (arising from adenine deamination), and alkylated bases such as 3-methyladenine and 7-methylguanine. Glycosylases that recognize other lesions, including pyrimidine dimers, have also been identified in some classes of organisms. Remember that AP sites also arise from the slow, spontaneous hydrolysis of the N-glycosyl bonds in DNA (see Fig. 8-30b).

25.2 DNA Repair 1031 5 1 3

1 MutS MutL MutH v- = MutL-MutS ATP. DNA helicase II exonuclease | or exonuclease X DNA polymerase III SSB that is used depends on the location of the cleavage site relative to the mismatch, as shown by the alternative pathways here. The resulting gap is filled in (dashed line) by DNA polymerase III, and the nick is sealed by DNA ligase (not shown). Once an AP site has been formed by a DNA glycosylase, another type of enzyme must repair it. The repair is not made by simply inserting a new base and re-forming the N-glycosyl bond. Instead, the deoxyribose 5'-phosphate left behind is removed and replaced with a new nucleotide. This process begins with one of the AP endonucleases, enzymes that cut the DNA

strand containing the AP site. The position of the incision relative to the AP site (5' or 3' to the site) varies with the type of AP endonuclease. A segment of DNA including the AP site is then removed, DNA polymerase I replaces the DNA, and DNA ligase seals the remaining nick (Fig. 25-24). In eukaryotes, nucleotide replacement is carried out by specialized polymerases, as described below. Nucleotide-Excision Repair DNA lesions that cause large distortions in the helical structure of DNA generally are repaired by the nucleotide-excision system, a repair pathway critical to the survival of all free-living organisms. In nucleotide-excision repair (Fig. 25-25), a multisubunit enzyme (excinuclease) hydrolyzes two phosphodiester bonds, one on either side of the distortion caused by the lesion. In *E. coli* and other bacteria, the enzyme system hydrolyzes the fifth phosphodiester bond on the 3' side and the eighth phosphodiester bond on the 5' side to generate a fragment of 12 to 13 nucleotides (depending

In humans and other eukaryotes, the enzyme system hydrolyzes the sixth phosphodiester bond on the 3' side and the twenty-second phosphodiester bond on the 5' side, FIGURE 25-24 DNA repair by the base-excision repair pathway. @ A DNA glycosylase recognizes a damaged base (in this case, a uracil) and cleaves between the base and deoxyribose in the backbone. @ An AP endonuclease cleaves the phosphodiester backbone near the AP site. @ DNA polymerase | initiates repair synthesis from the free 3' hydroxyl at the nick, removing (with its 5'3' exonuclease activity) and replacing a portion of the damaged strand. @ The nick remaining after DNA polymerase | has dissociated is sealed by DNA ligase. producing a fragment of 27 to 29 nucleotides. Following the dual incision, the excised oligonucleotides are released from the duplex and the resulting gap is filled—by DNA polymerase I in *E. coli* and DNA polymerase δ in humans. DNA ligase seals the nick. In *E. coli*, the key enzymatic complex is the ABC excinuclease, which has three subunits, UvrA (M, 104,000), UvrB (M, 78,000), and UvrC (M, 68,000). The term “excinuclease” is used to describe the unique capacity of this enzyme complex to catalyze two specific endonucleolytic cleavages, distinguishing this activity from that of standard endonucleases. A complex of the UvrA and UvrB proteins (A,B) scans the DNA and binds to the site of a lesion. The UvrA dimer then dissociates, leaving a tight UvrB-DNA complex. UvrC protein then binds to UvrB, and UvrB makes an incision at the fifth phosphodiester bond on the 3' side of the lesion. This is followed by a UvrC-mediated incision at the eighth phosphodiester bond on the 5' side. The resulting 12 to 13 nucleotide fragment is removed by UvrD helicase. The short gap thus created is filled in by DNA polymerase I and DNA ligase. This pathway (Fig. 25-25, left) is a primary repair route for many types of lesions, including cyclobutane pyrimidine dimers, 6-4 photoproducts (see Fig. 8-31), and several other types of base adducts including benzo[a]pyreneguanine, which is formed in DNA by exposure to cigarette smoke. The nucleolytic activity of the ABC excinuclease is novel in the sense that two cuts are made in the DNA. The mechanism of eukaryotic excinucleases is quite similar to that of the

bacterial enzyme, although 16 polypeptides with no similarity to the *E. coli* excinuclease subunits are required for the dual incision. As described in Chapter 26, some of the nucleotide excision repair and base-excision repair in eukaryotes is closely tied to transcription. Genetic deficiencies in nucleotide excision repair in humans give rise to a variety of serious diseases (see Box 25-1).

Direct Repair Several types of damage are repaired without removing a base or nucleotide. The best-characterized example is direct photoreactivation of cyclobutane pyrimidine dimers, a reaction promoted by DNA photolyases. Pyrimidine dimers result from a UV-induced reaction, and photolyases use energy derived from absorbed light to reverse the damage (Fig. 25-26). Photolyases generally contain two cofactors that serve as light-absorbing agents, or chromophores.

 repair in *E. coli* and humans. The general pathway of nucleotide-
 excision repair is similar in all organisms. @ An excinuclease binds
 to DNA at the site of a bulky lesion and cleaves the damaged DNA
 strand on either side of the lesion. @ The One of the chromophores
 is always FADHs. In *E. coli* and yeast, the other chromophore is a
 folate. The reaction mechanism entails the generation of free
 radicals. DNA photolyases are not present in the cells of placental
 mammals (which include humans). Additional examples can be seen
 in the repair of nucleotides with alkylation damage. The modified
 nucleotide O°-methylguanine forms in the presence of alkylating
 agents and is a common and highly mutagenic lesion (p. 302). It
 tends to pair with thymine rather than cytosine during replication,
 and therefore causes G = C to A = T mutations (Fig. 25-27). Direct
 repair of O°-methylguanine is carried out by O°-methylguanineDNA
 methyltransferase, a protein that catalyzes transfer of the methyl
 group of O°-methylguanine to one of its own Cys residues. This
 methyltransferase is not strictly an enzyme, because a single methyl
 transfer event permanently methylates the protein, making it
 inactive in this pathway. The consumption of an entire protein
 molecule to correct a single damaged base is another vivid
 illustration of the priority given to maintaining the integrity of
 cellular DNA. DNA segment—of 13 nucleotides (13 mer) or 29
 nucleotides (29 mer)—is removed with the aid of a helicase. @ The

 Guanine nucleotide O®-Methylguanine nucleotide A very different
 but equally direct mechanism is used to repair 1-methyladenine and
 3-methylcytosine. The amino groups of A and C residues are
 sometimes methylated when the DNA is single-stranded, and the
 methylation directly affects proper base pairing. In *E. coli*, oxidative
 demethylation of these alkylated nucleotides is mediated by the
 AlkB protein, a member of the a-ketoglutarate-Fe²⁺—dependent
 dioxygenase superfamily (Fig. 25-28). (See Box 4-3 for a description

of another member of this enzyme family.)

1034 DNA Metabolism A blue-light photon = 2 (300 to 500 nm) is absorbed by MTHFpolyGlu. The excited flavin (*FADH) donates an electron to the pyrimidine dimer to generate an unstable dimer radical. Energy derived from absorbed light is used to reverse the photoreaction that caused the lesion. The two chromophores in E. coli photolyase (M, 54,000), N⁵,N¹⁰-methenyltetrahydrofolylpolyglutamate (MTHFpolyGlu) and FADH₂, perform complementary functions. MTHF The Interaction of Replication Forks with DNA Damage Can Lead to Error-Prone Translesion DNA Synthesis The repair pathways considered to this point generally work only for lesions in double-stranded DNA, the undamaged strand providing the correct genetic information to restore the damaged strand to its original state. However, in certain types of lesions, such as double-strand breaks, double-strand cross-links, or lesions in a single-stranded DNA, the complementary strand is itself damaged or is absent. Double-strand breaks and lesions in single-stranded DNA most often *FADH₂ ac N a LG) be NH FADH₂ C N H O Flavin radical I I A rs The excitation energy 7 'e passes to FADHTM in the active site. Such lesions and DNA cross-links can also result from ionizing radiation and oxidative reactions. At a stalled bacterial replication fork, there are two avenues for repair. In the absence of a second strand, the information required for accurate repair must come from a separate, homologous chromosome. The repair system thus involves homologous genetic recombination. This recombinational DNA repair is considered in detail in Section 25.3. Under some conditions, a second repair pathway, error-prone translesion DNA

(a) $\text{H-N}^+ \text{C}(\text{H}_2)(\text{NH}_2)\text{C}(\text{O}^-)\text{NH}_2$ (Guanine) pairs with $\text{H-N}^+ \text{C}(\text{H})(\text{CH}_3)\text{C}(\text{O}^-)\text{NH}_2$ (Thymine) rather than $\text{H-N}^+ \text{C}(\text{H})(\text{NH}_2)\text{C}(\text{O}^-)\text{NH}_2$ (Cytosine). (b) If not repaired, this leads to a G = C to A = T mutation after replication. Translesion DNA synthesis (often abbreviated TLS), becomes available. When this pathway is active, DNA repair becomes significantly less accurate and a high mutation rate can result. In bacteria, error-prone translesion DNA synthesis is part of a cellular stress response to extensive DNA damage known, appropriately enough, as the SOS response. Some SOS proteins, such as the UvrA and UvrB proteins already described, are normally present in the cell but are induced to higher levels as part of the SOS response (Table 25-6). Additional SOS proteins participate in the pathway for error-prone repair; these include the UmuC and UmuD proteins ("Umu" from unmutable; lack of the umu gene function eliminates error-prone repair). The UmuD protein is cleaved $\text{O}_2 \text{CO} \rightarrow \text{CO}_2 + \text{COO}^-$ in the presence of H^+ : $\text{CH}_2\text{COO}^- + \text{H}^+ \rightarrow \text{CH}_3\text{COO}^-$ Succinate $\text{NH}_2\text{COO}^- + \text{H}^+ \rightarrow \text{NH}_3^+\text{COO}^-$ a-Ketoglutarate $\text{CH}_3\text{COO}^- + \text{H}^+ \rightarrow \text{CH}_3\text{COO}^-$ AlkB, Fe^{2+} o 1-Methyladenine $\text{COO}^- + \text{H}^+ \rightarrow \text{NH}_2\text{COO}^-$ J ie Sat $\text{CH}_3\text{COO}^- + \text{H}^+ \rightarrow \text{CH}_3\text{COO}^-$ a-Ketoglutarate AlkB, Fe^{2+} 3-Methylcytosine 25.2 DNARepair 1035 = methylation $\text{G} \rightarrow \text{A}$ $\text{C} \rightarrow \text{T}$ CH_3 -G $\rightarrow$ E replication replication Correctly paired DNA (no mutations)

FIGURE 25-29 DNA damage and its effect on DNA replication. If the replication fork encounters an unrepaired lesion, the replication fork stalls. If the lesion is a single-strand break (SSB), the fork can restart after a short delay. If the lesion is a double-strand break (DSB), the fork may collapse, leading to a double-strand break. A lesion is left behind in an unrepaired, single-stranded segment of the DNA (left); a strand break becomes a double-strand break (right). In each case the damage to one strand cannot be repaired by mechanisms described earlier in this chapter, because the complementary strand required for repair is damaged or absent. There are two possible avenues for repair: recombinational DNA repair (one pathway is described in Fig. 25-30) or, when lesions are unusually numerous, error-prone repair. The latter mechanism involves a novel DNA polymerase (DNA polymerase V, encoded by the *umuC* and *umuD* genes) that can replicate, albeit inaccurately, over many types of lesions. The repair mechanism is “error-prone” because mutations often result. The site of such a lesion, so this translesion replication is error-prone. Given the emphasis on the importance of genomic integrity throughout this chapter, the existence of a system that increases the rate of mutation may seem incongruous. However, we can think of this system as a desperation strategy. The *umuC* and *umuD* genes are fully induced as part of the SOS response in *E. coli*.

induced only late in the SOS response, and they are not activated for translesion synthesis initiated by UmuD cleavage unless the levels of DNA damage are particularly high and all replication forks are blocked. The mutations resulting from DNA polymerase V—mediated replication kill some cells and create deleterious mutations in others, but this is the biological price a species pays to overcome an otherwise insurmountable barrier to replication, as it permits at least a few mutant daughter cells to survive. Yet another DNA polymerase, DNA polymerase IV, is also induced during the SOS response. Replication by DNA polymerase IV, a product of the *dinB* gene, is also highly error-prone. The bacterial DNA polymerases IV and V are part of a family of TLS polymerases found in all organisms. These enzymes lack a proofreading exonuclease and possess a more open active site that accommodates damaged template nucleotides. The fidelity of base selection during replication can be reduced by a factor of 10^3 , lowering overall replication fidelity to one error in $\sim 1,000$ nucleotides. Mammals have many low-fidelity DNA polymerases of the TLS polymerase family. However, the presence of these enzymes does not necessarily translate into an unacceptable mutational burden, because most of these enzymes also have specialized functions in DNA repair. DNA polymerase η (eta), for example, promotes translesion synthesis primarily across cyclobutane T-T dimers. Few mutations result in this case, because the enzyme preferentially inserts two A residues across from the linked T residues. Several other low-fidelity polymerases, including DNA polymerases θ (theta), ι (iota), and κ (kappa), have specialized roles in eukaryotic base-excision repair. Each of these enzymes has a 5'-deoxyribose phosphate lyase activity in addition to its polymerase activity. After base removal by a glycosylase and backbone cleavage by an AP endonuclease, these polymerases remove the abasic site (a 5'-deoxyribose phosphate) and fill in the very short gap. The frequency of mutation due to DNA polymerase η activity is minimized by the very short lengths (often one nucleotide) of DNA synthesized. What emerges from research into cellular DNA repair systems is a picture of a DNA metabolism that maintains genomic integrity with multiple and often redundant systems. In the human genome, more than 130 genes encode proteins dedicated to the repair of DNA. In many cases, the loss of

function of one of these proteins results in genomic instability and an increased occurrence of oncogenesis (Box 25-1). These repair systems are often integrated with the DNA replication systems and are complemented by recombination systems, which we turn to next. BOX 25-1 E ADANA DNA Repair and Cancer Human cancers develop when genes that regulate normal cell division (oncogenes and tumor suppressor genes; Chapter 12) fail to function, are activated at the wrong time, or are altered. As a consequence, cells may grow out of control and form a tumor. The genes controlling cell division can be damaged by spontaneous mutation or overridden by the invasion of a tumor virus (Chapter 26). Not surprisingly, alterations in DNA repair genes that result in an increased rate of mutation can greatly increase an individual's susceptibility to cancer. Defects in the genes encoding the proteins involved in nucleotide excision repair, mismatch repair, recombinational repair, and error-prone translesion DNA synthesis have all been linked to human cancers. Clearly, DNA repair can be a matter of life and death. Nucleotide-excision repair requires a larger number of proteins in humans than in bacteria, although the overall pathways are very similar. Genetic defects that inactivate nucleotide-excision repair have been associated with several genetic diseases, the best studied of which is xeroderma pigmentosum (XP). Because nucleotide-excision repair is the sole repair pathway for pyrimidine dimers in humans, people with XP are extremely sensitive to light and readily develop sunlight-induced skin cancers. Most people with XP also have neurological abnormalities, presumably because of their inability to repair certain lesions caused by the high rate of oxidative metabolism in neurons. Defects in the genes encoding any of at least seven different protein components of the nucleotide-excision repair system can result in XP, giving rise to seven different genetic groups denoted XPA to XPG. Several of these proteins (notably those defective in XPB, XPD, and XPG) also play roles in transcription-coupled base-excision repair of oxidative lesions, described in Chapter 26. Most microorganisms have redundant pathways for the repair of cyclobutane pyrimidine dimers—making use of DNA photolyases and sometimes base excision repair as alternatives to nucleotide-excision repair—but humans and other placental mammals do not. This lack of a backup for nucleotide-excision repair for removing pyrimidine dimers has led to speculation that early mammalian

evolution involved small, furry, nocturnal animals with little need to repair UV damage. However, mammals do have a pathway for the translesion bypass of cyclobutane pyrimidine dimers, which involves DNA polymerase η . This enzyme preferentially inserts two A residues opposite a T-T pyrimidine dimer, minimizing mutations. People with a genetic condition in which DNA polymerase (continued on next page)

BOX 25-1 MEDICINE DNA Repair and Cancer

Human cancers develop when genes that regulate normal cell division (oncogenes and tumor suppressor genes; Chapter 12) fail to function, are activated at the wrong time, or are altered. As a consequence, cells may grow out of control and form a tumor. The genes controlling cell division can be damaged by spontaneous mutation or overridden by the invasion of a tumor virus (Chapter 26). Not surprisingly, alterations in DNA repair genes that result in an increased rate of mutation can greatly increase an individual's susceptibility to cancer. Defects in the genes encoding the proteins involved in nucleotide-excision repair, mismatch repair, recombinational repair, and error-prone translesion DNA synthesis have all been linked to human cancers. Clearly, DNA repair can be a matter of life and death.

Nucleotide-excision repair requires a larger number of proteins in humans than in bacteria, although the overall pathways are very similar. Genetic defects that inactivate nucleotide-excision repair have been associated with several genetic diseases, the best-studied of which is xeroderma pigmentosum (XP). Because nucleotide-excision repair is the sole repair pathway for pyrimidine dimers in humans, people with XP are extremely sensitive to light and readily develop sunlight-induced skin cancers. Most people

with XP also have neurological abnormalities, presumably because of their inability to repair certain lesions caused by the high rate of oxidative metabolism in neurons. Defects in the genes encoding any of at least seven different protein components of the nucleotide-excision repair system can result in XP, giving rise to seven different genetic groups denoted XPA to XPG. Several of these proteins (notably those defective in XPB, XPD, and XPG) also play roles in transcription-coupled base-excision repair of oxidative lesions, described in Chapter 26.

Most microorganisms have redundant pathways for the repair of cyclobutane pyrimidine dimers—making use of DNA photolyases and sometimes base-excision repair as alternatives to nucleotide-excision repair—but humans and other placental mammals do not. This lack of a backup for nucleotide-excision repair for removing pyrimidine dimers has led to speculation that early mammalian evolution involved small, furry, nocturnal animals with little need to repair UV damage. However, mammals do have a pathway for the translesion bypass of cyclobutane pyrimidine dimers, which involves DNA polymerase η . This enzyme preferentially inserts two A residues opposite a T-T pyrimidine dimer, minimizing mutations. People with a genetic condition in which DNA polymerase η

(continued on next page)

1038 DNA Metabolism BOX 25-1 E AVDA DNA Repair and Cancer (Continued) function is missing exhibit an XP-like illness known as XP-variant or XP-V. Clinical manifestations of XP-V are similar to those of the classic XP diseases, although mutation levels are higher in XP-V when cells are exposed to UV light. Apparently, the nucleotide excision repair system works in concert with DNA polymerase ϵ in normal human cells, repairing and/or bypassing pyrimidine dimers as needed to keep cell growth and DNA replication going. Exposure to UV light introduces a heavy load of pyrimidine dimers, and some must be bypassed by translesion synthesis to keep replication on track. When one system is missing, it is partly compensated for by the other. A loss of DNA polymerase ϵ activity leads to stalled replication forks and bypass of UV lesions by different, more mutagenic, translesion synthesis (TLS) polymerases. As when other DNA repair systems are absent, the resulting increase in mutations often leads to cancer. One of the most common inherited cancer-susceptibility syndromes is hereditary nonpolyposis colon cancer (HNPCC). This syndrome has been traced to defects in mismatch repair. Human and SUMMARY

25.2 DNA Repair > Cells have many systems for DNA repair. Mismatch repair in *E. coli* is directed by transient nonmethylation of (5')GATC sequences on the newly synthesized strand. Base-excision repair systems recognize and repair damage caused by environmental agents (such as radiation and alkylating agents) and spontaneous reactions of nucleotides. Some repair systems recognize and excise only damaged or incorrect bases, leaving an AP (abasic) site in the DNA. This is repaired by excision and replacement of the DNA segment containing the AP site. Nucleotide-excision repair systems recognize and remove a variety of bulky lesions and pyrimidine dimers. They excise a segment of the DNA strand including the lesion, leaving a gap that is filled in by DNA polymerase and ligase activities. Some DNA damage is repaired by direct reversal of the reaction causing the damage: pyrimidine dimers are directly converted to monomeric pyrimidines by a photolyase, and the methyl group of O⁶-methylguanine is removed by a methyltransferase. In bacteria, error-prone translesion DNA synthesis, involving TLS DNA polymerases, occurs in response to very heavy DNA damage. In other eukaryotic cells have several proteins analogous to the bacterial MutL and MutS proteins (see

Fig. 25-22). Defects in at least five different mismatch repair genes can give rise to HNPCC. The most prevalent are defects in the AMLH/ (human MutL homolog 1) and hMSH2 (human MutS homolog 2) genes. In individuals with HNPCC, cancer generally develops at an early age, with colon cancers being most common. Most human breast cancer occurs in women with no known predisposition. However, about 10% of cases are associated with inherited defects in two genes, BRCA1 and BRCA2. Human BRCA1 and BRCA2 are large proteins (1,834 and 3,418 amino acid residues, respectively) that interact with a wide range of other proteins involved in transcription, chromosome maintenance, DNA repair, and control of the cell cycle. BRCA2 has been implicated in the recombinational DNA repair of double-strand breaks. However, the precise molecular function of BRCA1 and BRCA2 in these various cellular processes is not yet clear. Women with defects in either the BRCA1/ or BRCA2 gene have a greater than 80% chance of developing breast cancer. eukaryotes, similar polymerases have specialized roles in DNA repair that minimize the introduction of mutations.

25.3 DNA Recombination

The rearrangement of genetic information within and among DNA molecules encompasses a variety of processes, collectively placed under the heading of genetic recombination. The practical applications of DNA rearrangements in altering the genomes of increasing numbers of organisms are now being explored (Chapter 9). Genetic recombination events fall into at least three general classes. Homologous genetic recombination (also called general recombination) involves genetic exchanges between any two DNA molecules (or segments of the same molecule) that share an extended region of nearly identical sequence. The actual sequence of bases is irrelevant, as long as it is similar in the two DNAs. In site-specific recombination the exchanges occur only at a particular DNA sequence. DNA transposition is distinct from both other classes in that it usually involves a short segment of DNA with the remarkable capacity to move from one

Barbara McClintock, 1902-1992

function is missing exhibit an XP-like illness known as XP-variant or XP-V. Clinical manifestations of XP-V are similar to those of the classic XP diseases, although mutation levels are higher in XP-V when cells are exposed to UV light. Apparently, the nucleotide-excision repair system works in concert with DNA polymerase η in normal human cells, repairing and/or bypassing pyrimidine dimers as needed to keep cell growth and DNA replication going. Exposure to UV light introduces a heavy load of pyrimidine dimers, and some must be bypassed by translesion synthesis to keep replication on track. When one system is missing, it is partly compensated for by the other. A loss of DNA polymerase η activity leads to stalled replication forks and bypass of UV lesions by different, more mutagenic, translesion synthesis (TLS) polymerases. As when other DNA repair systems are absent, the resulting increase in mutations often leads to cancer.

One of the most common inherited cancer-susceptibility syndromes is hereditary nonpolyposis colon cancer (HNPCC). This syndrome has been traced to defects in mismatch repair. Human and

other eukaryotic cells have several proteins analogous to the bacterial MutL and MutS proteins (see Fig. 25-22). Defects in at least five different mismatch repair genes can give rise to HNPCC. The most prevalent are defects in the *hMLH1* (human MutL homolog 1) and *hMSH2* (human MutS homolog 2) genes. In individuals with HNPCC, cancer generally develops at an early age, with colon cancers being most common.

Most human breast cancer occurs in women with no known predisposition. However, about 10% of cases are associated with inherited defects in two genes, *BRCA1* and *BRCA2*. Human *BRCA1* and *BRCA2* are large proteins (1,834 and 3,418 amino acid residues, respectively) that interact with a wide range of other proteins involved in transcription, chromosome maintenance, DNA repair, and control of the cell cycle. *BRCA2* has been implicated in the recombinational DNA repair of double-strand breaks. However, the precise molecular function of *BRCA1* and *BRCA2* in these various cellular processes is not yet clear. Women with defects in either the *BRCA1* or *BRCA2* gene have a greater than 80% chance of developing breast cancer.

location in a chromosome to another. These “jumping genes” were first observed in maize in the 1940s by Barbara McClintock. There is in addition a wide range of unusual genetic rearrangements for which no mechanism or purpose has yet been proposed. Here we focus on the three general classes. The functions of genetic recombination systems are as varied as their mechanisms. They include roles in specialized DNA repair systems, specialized activities in DNA replication, regulation of expression of certain genes, facilitation of proper chromosome segregation during eukaryotic cell division, maintenance of genetic diversity, and implementation of programmed genetic rearrangements during embryonic development. In most cases, genetic recombination is closely integrated with other processes in DNA metabolism, and this becomes a theme of our discussion.

Bacterial Homologous Recombination Is a DNA Repair Function In bacteria, homologous genetic recombination is primarily a DNA repair process and in this context (as noted in Section 25.2) is referred to as recombinational DNA repair. It is usually directed at the reconstruction of replication forks that have stalled or collapsed at the site of DNA damage. Homologous genetic recombination can also occur during conjugation (mating), when chromosomal DNA is transferred from one bacterial cell (donor) to another (recipient). Recombination during conjugation, although rare in wild bacterial populations, contributes to genetic diversity. An example of what happens when a replication fork encounters DNA damage is shown in Figure 25-30. A common feature of the DNA repair pathways

FIGURE 25-30 Recombinational DNA repair at a collapsed replication fork. When a replication fork encounters a break in one of the template strands, one arm of the fork is lost and the replication fork collapses. The 5'-ending strand at the break is degraded to create a single-stranded 3" extension, which is then used in a strand invasion process, pairing the invading single strand with its complementary strand within the adjacent duplex. Migration of the branch (inset) can create a Holliday intermediate. Cleavage of the Holliday intermediate by specialized nucleases, followed by ligation, restores a viable replication fork. The replisome is reloaded onto this structure (not shown), and

replication continues. Arrowheads represent 3' ends. <— Branch migration 5 Holliday intermediate (4) Holliday intermediate resolution and ligation

1040 DNA Metabolism illustrated in Figures 25-22 to 25-25 is that they introduce a transient break into one of the DNA strands. If a replication fork encounters a damaged site under repair near a break in one of the template strands, one arm of the replication fork becomes disconnected by a double-strand break and the fork collapses. The end of that break is processed by degrading the 5'-ending strand. The resulting 3' single-strand extension is bound by a recombinase that uses it to promote strand invasion: the 3' end invades the intact duplex DNA connected to the other arm of the fork and pairs with its complementary sequence. This creates a branched DNA structure (a point where three DNA segments come together). The DNA branch can be moved in a process called branch migration to create an X-like crossover structure known as a Holliday intermediate, named after researcher Robin Holliday, who first postulated its existence. The Holliday intermediate is then resolved by a special class of nuclease. The overall process reconstructs the replication fork. In *E. coli*, the DNA end-processing is promoted by the RecBCD nuclease/helicase. The RecBCD enzyme binds to linear DNA at a free (broken) end and moves inward along the double helix, unwinding and degrading the DNA in a reaction coupled to ATP hydrolysis (Fig. 25-31). The RecB and RecD subunits are helicase motors, with RecB moving 3'→5' along one strand and RecD moving 5'→3' along the other strand. The activity of the enzyme is altered when it interacts with a sequence referred to as *chi*, (5')GCTGGTGG, which binds tightly to a site on the RecC subunit. From that point, degradation of the strand with a 3' terminus is greatly reduced, but degradation of the 5'-terminal strand is increased. This process creates a single-stranded DNA with a 3' end, which is used during subsequent steps in recombination. The 1,009 *chi* sequences scattered throughout the *E. coli* genome enhance the frequency of recombination about 5- to 10-fold within 1,000 bp of the *chi* site. The enhancement declines as the distance from

FIGURE 25-31 The RecBCD helicase/nuclease. (a) A cutaway view of the RecBCD enzyme structure as it is bound to DNA (PDB ID 1W36). The subunits are shown in different colors, with the DNA entering the structure at left and the unwound DNA strands (not part of the solved structure) are modeled as exiting to the right. A bulbous protein structure called a pin, part of the RecC subunit, facilitates the separation of strands. (b) Activities of the RecBCD

enzyme at a DNA end. The RecB and RecD subunits are helicases, molecular motors that propel the complex along the DNA, a process that requires ATP; RecB degrades both strands as the complex travels, cleaving the 3'-ending strand more often than the 5'-ending strand. When a chi site is encountered on the 3'-ending strand, the RecC subunit binds to it, halting the advance of this strand through the complex. The 5'-ending strand continues to be degraded as the 3'-ending strand is looped out, eventually creating a 3' single-stranded extension. RecA protein (not shown) is finally loaded onto the processed DNA by the RecBCD enzyme. the chi site increases. Sequences that enhance recombination frequency have also been identified in several other organisms. The bacterial recombinase is the RecA protein. in that its active form is an ordered, helical filament of up to several thousand subunits that assemble cooperatively on DNA (Fig. 25-32). This filament usually forms on single-stranded DNA, such as that produced extension (fast) 513? disassembly 5537 Amino-terminal Carboxyl domain terminal i s domain 3 he S 3 1 Core domain 25.3 DNA Recombination 1041 by the RecBCD enzyme. Its formation is not as straightforward as shown in Figure 25-32, since the singlestranded DNA-binding protein (SSB) is normally present and specifically impedes the binding of the first few subunits to DNA (filament nucleation). The RecBCD enzyme acts directly as a RecA loader, facilitating the nucleation of a RecA filament on single-stranded DNA that is coated with SSB. The filaments assemble and disassemble in a 5'—3' direction. Many other bacterial proteins regulate the formation and disassembly of RecA filaments. RecA protein promotes the central steps of homologous recombination, including the DNA strand invasion step of Figure 25-31 and a number of other strand exchange reactions in vitro. After strand invasion has occurred, branch migration is promoted by a complex called RuvAB (Fig. 25-33a). Once a Holliday intermediate has been created, it can be cleaved by a specialized nuclease called RuvC (Fig. 25-33b), and nicks are sealed with DNA ligase. A viable replication fork structure is thus reconstructed, as outlined in Figure 25-31. After the recombination steps are completed, the replication fork reassembles in a process called originindependent restart of replication. Four proteins (PriA, PriB, PriC, and DnaT) act with DnaC to load the DnaB helicase onto the reconstructed replication fork. The DnaG primase then synthesizes an RNA primer, and DNA polymerase reassembles on DnaB to restart DNA synthesis. Originally discovered as a component required for the replication of 6X174 DNA in vitro, a complex of PriA, PriB, PriC, and DnaT, along with DnaB, DnaC, and DnaG, is now termed the replication restart primosome. Restart of the replication fork also requires DNA polymerase II, in a role not yet defined; this polymerase II activity gives way to DNA polymerase III activity for the extensive replication generally required to complete the chromosome. In this way, the process of recombination is tightly intertwined with replication. One process of DNA metabolism supports the other. Eukaryotic Homologous Recombination Is Required for Proper Chromosome Segregation

during Meiosis In eukaryotes, homologous genetic recombination can have several roles in replication and cell division, including the repair of stalled replication forks. Recombination

FIGURE 25-32

RecA protein filaments. RecA and other recombinases in this class function as filaments of nucleoprotein. (a) Filament formation proceeds in discrete nucleation and extension steps. Nucleation is the addition of the first few RecA subunits. Extension occurs by adding RecA subunits so that the filament grows in the 5'—3' direction. When disassembly occurs, subunits are subtracted from the trailing end. (b) Colorized electron micrograph of a RecA filament bound to DNA. (c) Segment of a RecA filament with four helical turns (24 RecA subunits; derived from PDB ID 3CMX). Notice the bound double-stranded DNA in the center. The core domain of RecA is structurally related to the domains in helicases.

1042 DNA Metabolism (a) Incoming DNA f t— Outgoing 4

DNA Incoming DNA (b) Junction cleavage at opposing DNA occurs with the highest frequency during meiosis, the process by which diploid germ-line cells with two sets of chromosomes divide to produce haploid gametes (sperm cells or ova) in animals (haploid spores in plants)—each gamete having only one member of each chromosome pair (Fig. 25-34). Meiosis begins with replication of the DNA in the germ-line cell so that each DNA molecule is present in four copies. Each set of four homologous chromosomes (tetrad) exists as two pairs of sister chromatids, and the sister chromatids remain associated at their centromeres. The cell then goes through two rounds of cell division without an intervening round of DNA replication. In the first cell division, the two pairs of sister chromatids are segregated into daughter cells. In the second cell division, the two chromosomes in each sister chromatid pair are segregated into new daughter cells. In each division, the chromosomes to be segregated are drawn into the daughter cells by spindle fibers attached to opposite poles of the dividing cell. The two successive divisions reduce the DNA content to the haploid level in each gamete. Proper chromosome segregation into daughter cells requires that physical links exist between the homologous chromosomes to be segregated. As the \(\backslash\) (DO FIGURE 25-33

Catalysis of DNA branch migration and Holliday intermediate resolution by the RuvA, RuvB, and RuvC proteins. (a) The RuvA protein binds directly to a Holliday intermediate where the four DNA arms come together. The hexameric RuvB protein is a DNA translocase. Two hexamers bind to opposing arms of the Holliday intermediate and propel the DNA outward in a reaction coupled to ATP hydrolysis. The branch thus moves. (b) RuvC is a specialized nuclease that binds to the — Outgoing DNA RuvAB complex and cleaves the Holliday intermediate on opposing sides of the junction (red arrows) so that two contiguous DNA arms remain in each product. spindle fibers attach to the centromeres of chromosomes and start to pull, the links between homologous chromosomes create tension. This tension, sensed by cellular mechanisms not yet understood, signals that this pair of chromosomes or sister chromatids is properly aligned for segregation. Once the tension is sensed, the links are gradually dissolved and segregation proceeds. If improper spindle fiber attachment occurs (e.g., if the centromeres

of a chromosome pair are attached to the same cellular pole), a cellular kinase senses the lack of tension and activates a system that removes the spindle attachments, allowing the cell to try again. During the second meiotic division, the centromeric attachments between the sister chromatids, augmented by cohesins deposited during replication (see Fig. 24-34), provide the needed physical links to guide segregation. However, during the first meiotic cell division, the two pairs of sister chromatids to be segregated are not related by a recent replication event and are not linked by cohesins or any other physical association. Instead, the homologous pairs of sister chromatids are aligned and new links are created by recombination, a process involving the breakage and rejoining of DNA

 (Fig. 25-35). This exchange, also referred to as crossing over, can be
 observed with the light microscope. Crossing over links the two
 pairs of sister chromatids together at points called chiasmata
 (singular, chiasma). Also during crossovers, genetic material is
 exchanged between the pairs of sister chromatids. These exchanges
 also increase genetic diversity in the resulting gametes. The
 importance of meiotic recombination to proper chromosomal
 segregation is well illustrated by the physiological and societal
 consequences of their failure (Box 25-2).

25.3 DNA Recombination

1043 **FIGURE 25-34 Meiosis in animal germ-line cells.** The
 chromosomes of a hypothetical diploid germ-line cell (four
 chromosomes; two homologous pairs) replicate and are held
 together at their centromeres. Each replicated double-stranded DNA
 molecule is called a chromatid (sister chromatid). In prophase I, just
 before the first meiotic division, the two homologous sets of
 chromatids align to form tetrads, held together by covalent links at
 homologous junctions (chiasmata). Crossovers occur within the
 chiasmata (see Fig. 25-35). These transient associations between
 homologs ensure that the two tethered chromosomes segregate
 properly in the next step, when attached spindle fibers pull them
 toward opposite poles of the dividing cell in the first meiotic
 division. The products of this division are two daughter cells each
 with two pairs of different sister chromatids. The pairs now line up
 across the equator of the cell in preparation for separation of the
 chromatids (now called chromosomes). The second meiotic division
 produces four haploid daughter cells that can serve as gametes.
 Each has two chromosomes, half the number of the diploid germ-
 line cell. The chromosomes have re-sorted and recombined.
 Crossing over is not an entirely random process, and “hot spots”
 have been identified on many eukaryotic chromosomes. However,
 the assumption that crossing over can occur with equal probability
 at almost any point along the length of two homologous
 chromosomes remains a reasonable approximation in many cases,
 and it is this assumption that permits the genetic mapping of genes
 on a particular chromosome. The frequency of homologous

recombination in any region separating two points on a chromosome is roughly proportional to the distance between the points, and this allows determination of the relative positions of and distances between different genes. The independent assortment of unlinked genes on different chromosomes (Fig. 25-36) makes another major contribution to the genetic diversity of the gametes. These genetic realities guide many of the modern applications of genomics, such as defining haplotypes (see Fig. 9-30) or searching for disease genes in the human genome (see Fig. 9-34). Homologous recombination thus serves at least three identifiable functions in eukaryotes: (1) it contributes to the repair of several types of DNA damage; (2) it provides, in eukaryotic cells, a transient physical link between chromatids that promotes the orderly segregation of chromosomes at the first meiotic cell division; and (3) it enhances genetic diversity in a population. Recombination during Meiosis Is Initiated with Double-Strand Breaks A likely pathway for homologous recombination during meiosis is outlined in Figure 25—35a. The model has four key features. First, homologous chromosomes are aligned. Second, a double-strand break in a DNA molecule is created and then the exposed ends are processed by an exonuclease, leaving a single-strand extension with a free 3'-hydroxyl group at the broken end (step @). Third, the exposed 3' ends invade the intact duplex DNA of the homolog, and this is followed by

FIGURE 25-35 Recombination during prophase I in meiosis. (a) Model of double-strand break repair for homologous genetic recombination. The two homologous chromosomes (one shown in red, the other blue) involved in this recombination event have identical or very nearly identical sequences. Each of the two genes shown has different alleles on the two chromosomes. The steps are described in the text. (b) Crossing over occurs during prophase I of meiosis. The several stages of prophase I are aligned with the recombination processes that are occurring in part (a).

25.3 DNA Recombination 1045 Double-strand breaks are introduced and processed in the leptotene stage. The strand invasion and completion of crossover occur later. As homologous sequences in the two pairs of sister chromatids are aligned in the zygotene stage, synaptonemal complexes form and strand invasion occurs. The homologous chromosomes are tightly aligned by the pachytene stage. (c) Homologous chromosomes of a grasshopper are viewed at successive stages of meiotic prophase I. The chiasmata become visible in the diplotene stage.

BOX 25-2 **⚡ MEDICINE** Why Proper Chromosomal Segregation Matters When chromosomal alignment and recombination are not correct and complete in meiosis I, segregation of chromosomes can go awry. One result may be aneuploidy, a condition in which a cell has the wrong number of chromosomes. The haploid products of meiosis (gametes or spores) may have no copies or two copies of a chromosome. When a gamete with two copies of a chromosome joins with a gamete with one copy of a chromosome during fertilization, cells in the resulting embryo have three copies of that chromosome (they are trisomic). In *S. cerevisiae*, aneuploidy resulting from errors in meiosis occurs at a rate of about 1 in 10,000 meiotic events. In fruit flies, the rate is about 1 in a few thousand. Rates of aneuploidy in mammals are considerably higher. In mice, the rate is 1 in 100, and it is even higher in other mammals. The rate of aneuploidy in fertilized human eggs has been estimated as 10% to 30%; most of these aneuploid cells are monosomies (they have a single copy of a chromosome) or trisomies. This is almost certainly an underestimate. Most trisomies are lethal and many result in miscarriage long before the pregnancy is detected. Aneuploidy is the leading cause of pregnancy loss. The few trisomic fetuses that survive to birth generally have three copies of chromosome 13, 18,

or 21 (trisomy 21 is Down syndrome). Abnormal complements of the sex chromosomes are also found in the human population. Almost all monosomies are fatal in the early stages of fetal development. The societal consequences of aneuploidy in humans are considerable. Aneuploidy is the leading genetic cause of developmental and mental disabilities. At the heart of these high rates is a feature of meiosis in female mammals that has special significance for the human species. In a human male, germ-line cells begin to undergo meiosis at puberty, and each meiotic event requires a relatively short time. In contrast, meiosis in the germline cells of human females is a highly protracted process. The production of an egg begins before a female is born—with the onset of meiosis in the fetus, at 12 to 13 weeks of gestation. Meiosis is initiated in all the developing fetal germ-line cells over a period of a few weeks. The cells proceed through much of meiosis I. Chromosomes line up and generate crossovers, continuing just beyond the pachytene phase (see Fig. 25-35)—and then the process stops. The chromosomes enter an arrested phase called the dictyate stage, with the crossovers in place, a kind of suspended animation where they remain as the female matures—typically from 13 to 50 years. It is not until sexual maturity that individual germ-line cells continue through the two meiotic cell divisions to produce egg cells. Between the onset of the dictyate stage and the final completion of meiosis, something may happen that disrupts or damages the crossovers linking homologous chromosomes in the germ-line cells. As a woman ages, the rate of trisomy in the egg cells she produces increases, dramatically so as she approaches menopause (Fig. 1). There are many hypotheses on why this occurs, and several different factors may play a role. However, most of the hypotheses are centered on recombination crossovers in meiosis I and their stability over the protracted dictyate stage. It is not yet clear what medical steps could be taken to reduce the incidence of aneuploidy in females of child-bearing age. What is revealed is the inherent importance of recombination and crossover generation in human meiosis.

35 Incidence of trisomy (% of clinically recognized pregnancies) | 15 30 Maternal age

FIGURE 1 The increasing incidence of human trisomy with increasing age of the mother.

When chromosomal alignment and recombination are not correct and complete in meiosis I, segregation of chromosomes can go awry. One result may be aneuploidy, a condition in which a cell has the wrong number of chromosomes. The haploid products of meiosis (gametes or spores) may have no copies or two copies of a chromosome. When a gamete with two copies of a chromosome joins with a gamete with one copy of a chromosome during fertilization, cells in the resulting embryo have three copies of that chromosome (they are trisomic).

In *S. cerevisiae*, aneuploidy resulting from errors in meiosis occurs at a rate of about 1 in 10,000 meiotic events. In fruit flies, the rate is about 1 in a few thousand. Rates of aneuploidy in mammals are considerably higher. In mice, the rate is 1 in 100, and it is even higher in other mammals. The rate of aneuploidy in fertilized human eggs has been estimated as 10% to 30%; most of these aneuploid cells are monosomies (they have a single copy of a chromosome) or trisomies. This is almost certainly an underestimate. Most trisomies are lethal and many result in miscarriage long before the pregnancy is detected. Aneuploidy is the leading cause of pregnancy loss. The few trisomic fetuses that survive to birth generally have three copies of chromosome 13, 18, or 21 (trisomy 21 is Down syndrome). Abnormal complements of the sex chromosomes are also found in the human population. Almost all monosomies are fatal in the early stages of fetal development. The societal consequences of aneuploidy in humans are considerable. Aneuploidy is the leading genetic cause of developmental and mental disabilities. At the heart of these high rates is a feature of meiosis in female mammals that has special significance for the human species.

In a human male, germ-line cells begin to undergo meiosis at puberty, and each meiotic event requires a relatively short time. In contrast, meiosis in the germ-line cells of human females is a highly protracted process. The production of an egg begins before a female is born—with the onset of meiosis in the fetus, at 12 to 13 weeks of gestation. Meiosis is initiated in all the developing fetal germ-line cells over a period of a few weeks. The cells proceed through much of meiosis I. Chromosomes line up and generate crossovers, continuing just beyond the pachytene phase (see Fig. 25-35)—and

then the process stops. The chromosomes enter an arrested phase called the dictyate stage, with the crossovers in place, a kind of suspended animation where they remain as the female matures—typically from 13 to 50 years. It is not until sexual maturity that individual germ-line cells continue through the two meiotic cell divisions to produce egg cells.

Between the onset of the dictyate stage and the final completion of meiosis, something may happen that disrupts or damages the crossovers linking homologous chromosomes in the germ-line cells. As a woman ages, the rate of trisomy in the egg cells she produces increases, dramatically so as she approaches menopause (Fig. 1). There are many hypotheses on why this occurs, and several different factors may play a role. However, most of the hypotheses are centered on recombination crossovers in meiosis I and their stability over the protracted dictyate stage.

It is not yet clear what medical steps could be taken to reduce the incidence of aneuploidy in females of child-bearing age. What is revealed is the inherent importance of recombination and crossover generation in human meiosis.

FIGURE 25-36 The contribution of independent assortment to genetic diversity. In this example, the chromosomes have already been replicated to create two pairs of sister chromatids for two chromosomes. Blue and red distinguish the sister chromatids of each pair. One gene on each chromosome is highlighted, with different alleles (A or a, B or b) in branch migration and/or replication to create a pair of Holliday intermediates (steps ③ to ④). Fourth, cleavage of the two crossovers creates either of two pairs of complete recombinant products (step ⑤). Note the similarity of these steps to the bacterial recombinational repair processes outlined in Figure 25-30. In this double-strand break repair model for recombination, the 3' ends are used to initiate the genetic exchange. Once paired with the complementary strand on the intact homolog, a region of hybrid DNA is created that contains complementary strands from two different parent DNAs (the product of step ③ in Fig. 25-35a). Each of the 3' ends can then act as a primer for DNA replication. Meiotic homologous recombination can vary in many details from one species to another, but most of the steps outlined above are generally present in some form. There are two ways to cleave, or "resolve," the Holliday intermediate with a RuvC-like nuclease so that the two products carry genes in the same linear order as in the substrates—the original, un-recombined chromosomes (step ⑤). If cleaved one way, the DNA flanking the region containing the hybrid DNA is not recombined; if cleaved the other way, the flanking DNA is recombined. Both outcomes are observed in vivo. The homologous recombination illustrated in Figure 25-35 is a very elaborate process that is essential to accurate chromosome segregation. Its molecular consequences for the generation of genetic diversity are subtle. To understand how this process contributes to diversity, we should keep in mind that the two homologous chromosomes that undergo recombination are not the homologs. Independent assortment can lead to gametes with any combination of the alleles present on the two different chromosomes. Crossing over (not shown here; see Fig. 25-34) would also contribute to genetic diversity in a typical meiotic sequence.

necessarily identical. The linear array of genes may be the same, but the base sequences in some of the genes may differ slightly (in different alleles). In a human, for example, one chromosome may contain the allele for hemoglobin A (normal hemoglobin) while the other contains the allele for hemoglobin S (the sickle-cell mutation). The difference may consist of no more than one base pair among millions. Homologous recombination does not change the linear array of genes, but it can determine which alleles become linked on a single chromosome and are thereby passed to the next generation together. The independent assortment of different chromosomes (Fig. 25-36) determines which gene alleles from different chromosomes are inherited together. Site-Specific Recombination Results in Precise DNA Rearrangements Homologous genetic recombination, the type we have discussed so far, can involve any two homologous sequences. The second general type of recombination, site-specific recombination, is a very different type of process: recombination is limited to specific sequences. Recombination reactions of this type occur in virtually every cell, filling specialized roles that vary greatly from one species to another. Examples include regulation of the expression of certain genes and promotion of programmed DNA rearrangements in embryonic development or in the replication cycles of some viral and plasmid DNAs. Each site-specific recombination system consists of an enzyme called a recombinase and a short

Recombinase (20 to 200 bp), unique DNA sequence where the recombinase acts (the recombination site). One or more auxiliary proteins may regulate the timing or outcome of the reaction. There are two general classes of site-specific recombination systems, which rely on either Tyr or Ser residues in the active site. In vitro studies of many site-specific recombination systems in the tyrosine class have elucidated some general principles, including the fundamental reaction pathway 25.3

DNARecombination 1047 (b) FIGURE 25-37 A site-specific recombination reaction. (a) The reaction shown here is for a common class of site-specific recombinases called integrase-class recombinases (named after bacteriophage λ integrase, the first recombinase characterized). These enzymes use Tyr residues as nucleophiles at the active site. The reaction is carried out within a tetramer of identical subunits. Recombinase subunits bind to a specific sequence, the recombination site. € One strand in each DNA is cleaved at particular points in the sequence. The nucleophile is the —OH group of an active-site Tyr residue, and the product is a covalent phosphotyrosine link between protein and DNA @. After isomerization ©, the cleaved strands join to new partners, producing a Holliday intermediate. Steps @ and @ complete the reaction by a process similar to the first two steps. The original sequence of the recombination site is regenerated after recombining the DNA flanking the site. These steps occur within a complex of multiple recombinase subunits that sometimes includes other proteins not shown here. (b) Surface contour model of a four-subunit integrase-class recombinase called the Cre recombinase, bound to a Holliday intermediate (shown with light blue and dark blue helix strands). The protein has been rendered transparent so that the bound DNA is visible (derived from PDB ID 3CRX). Another group of recombinases, called the resolvase/invertase family, use a Ser residue as nucleophile at the active site. strands are rejoined to new partners to form a Holliday intermediate, with new phosphodiester bonds created at the expense of the protein-DNA linkage (step @). An isomerization then occurs (step @), and the process is repeated at a second point within each of the two recombination sites (steps @ and @). In the systems that employ an active-site Ser residue, both strands of each recombination site are cut concurrently and rejoined to new partners without the Holliday

intermediate. In both types of system, the exchange is always reciprocal and precise, regenerating the recombination sites when the reaction is complete. We can view a recombinase as a site-specific endonuclease and ligase in one package. The sequences of the recombination sites recognized by site-specific recombinases are partially asymmetric (nonpalindromic), and the two recombining sites align in the same orientation during the recombinase reaction. The outcome depends on the location and orientation of the recombination sites. If the two sites are on the same DNA molecule, the reaction either inverts or deletes the

1048 DNA Metabolism Inversion Sites of exchange pe) | EM > 9 (a) FIGURE 25-38 Effects of site-specific recombination. The outcome of site-specific recombination depends on the location and orientation of the recombination sites (red and green) in a double-stranded DNA molecule. Orientation here (shown by arrowheads) refers to the order of nucleotides in the recombination site, not the 5'—3' direction. Intervening DNA, determined by whether the recombination sites have the opposite or the same orientation, respectively. If the sites are on different DNAs, the recombination is intermolecular; if one or both DNAs are circular, the result is an insertion. Some recombinase systems are highly specific for one of these reaction types and act only on sites with particular orientations. Complete chromosomal replication can require site-specific recombination. Recombinational DNA repair of a circular bacterial chromosome, while essential, sometimes generates deleterious byproducts. The resolution of a Holliday intermediate at a replication fork by a nuclease such as RuvC, followed by completion of replication, can give rise to one of two products: the usual two monomeric chromosomes or a contiguous dimeric chromosome (Fig. 25-39). In the latter case, the covalently linked chromosomes cannot be segregated to daughter cells at cell division and the dividing cells become “stuck.” A specialized site-specific recombination system in *E. coli*, the XerCD system, converts the dimeric chromosomes to monomeric chromosomes so that cell division can proceed. The reaction is a site-specific deletion (Fig. 25—38b). This FIGURE 25-39 DNA deletion to undo a deleterious effect of recombinational DNA repair. The resolution of a Holliday intermediate during recombinational DNA repair (Cif cut at the points indicated by red arrows) can generate a contiguous dimeric chromosome. A specialized site-specific recombinase in *E. coli*, XerCD, converts the dimer to monomers, allowing chromosome segregation and cell division to proceed. (b) Recombination sites with the same orientation, either on one DNA molecule, producing a deletion, or on two DNA molecules, producing an insertion. Fork undergoing recombinational DNA repair termination of replication Dimeric genome + resolution to monomers by XerCD system C_D

is another example of the close coordination between DNA recombination processes and other aspects of DNA metabolism.

Transposable Genetic Elements Move from One Location to Another

We now consider the third general type of recombination system: recombination that allows the movement of transposable elements, or transposons. These segments of DNA, found in virtually all cells, move, or “jump,” from one place on a chromosome (the donor site) to another on the same or a different chromosome (the target site). DNA sequence homology is not usually required for this movement, called transposition; the new location is determined more or less randomly. Insertion of a transposon in an essential gene could kill the cell, so transposition is tightly regulated and usually very infrequent. Transposons are perhaps the simplest of molecular parasites, adapted to replicate passively within the chromosomes of host cells. In some cases they carry genes that are useful to the host cell, and thus exist in a kind of symbiosis with the host. Bacteria have two classes of transposons. Insertion sequences (simple transposons) contain only the sequences required for transposition and the genes for the proteins (transposases) that promote the process. Complex transposons contain one or more genes in addition to those needed for transposition. These extra genes might, for example, confer resistance to antibiotics and thus enhance the survival chances of the host cell. The spread of antibiotic-resistance elements among disease-causing bacterial populations that is rendering some antibiotics ineffectual (p. 981) is mediated in part by transposition. W

Bacterial transposons vary in structure, but most have short repeated sequences at each end that serve as binding sites for the transposase. When transposition occurs, a short sequence at the target site (5 to 10 bp) is duplicated to form an additional short repeated sequence that flanks each end of the inserted transposon (Fig. 25-40). These duplicated segments result from the cutting mechanism used to insert a transposon into the DNA at a new location. There are two general pathways for transposition in bacteria. In direct (or simple) transposition (Fig. 25-41, left), cuts on each side of the transposon excise it, and the transposon moves to a new location. This leaves a double-strand break in the donor DNA that must be repaired. At the target site, a staggered cut is made (as in Fig. 25—40), the transposon is inserted into the break, and DNA replication fills in the gaps to duplicate the

target site sequence. In replicative transposition (Fig. 25-41, right), the entire transposon is replicated, leaving a copy behind at the donor location. A cointegrate is an intermediate in this process, consisting of the donor region covalently linked to DNA at the target site. A cointegrate is an intermediate in this process, consisting of the donor region covalently linked to DNA at the target site. A cointegrate is an intermediate in this process, consisting of the donor region covalently linked to DNA at the target site.

FIGURE 25-40 Duplication of the DNA sequence at a target site when a transposon is inserted. The sequences that are duplicated following transposon insertion are shown in red. These sequences are generally only a few base pairs long, so their size relative to that of a typical transposon is greatly exaggerated in this drawing.

Two complete copies of the transposon are present in the cointegrate, both having the same relative orientation in the DNA. In some well-characterized transposons, the cointegrate intermediate is converted to products by site-specific recombination, in which specialized recombinases promote the required deletion reaction. Eukaryotes also have transposons, structurally similar to bacterial transposons, and some use similar transposition mechanisms. In other cases, however, the mechanism of transposition seems to involve an RNA intermediate. Evolution of these transposons is intertwined with the evolution of certain classes of RNA viruses. Both are described in the next chapter.

Immunoglobulin Genes Assemble by Recombination Some DNA rearrangements are a programmed part of development in eukaryotic organisms. An important example is the generation of complete immunoglobulin genes from separate gene segments in vertebrate genomes. A human (like other mammals) is capable of producing millions of different immunoglobulins (antibodies) with distinct binding specificities, even though the human genome contains only ~29,000 genes. Recombination allows an organism to produce an extraordinary diversity of antibodies from a limited DNA-coding capacity. Studies of the recombination mechanism reveal a close relationship to DNA transposition and suggest that this system for generating antibody diversity may have evolved from an ancient cellular invasion of transposons.

Immunoglobulins consist of two heavy and two light polypeptide chains (see Fig. 5-21). Each chain has two regions, a variable region, with a sequence that differs greatly from one immunoglobulin to another, and a region that is virtually constant within a class of immunoglobulins. There are also two distinct families of light chains, kappa and lambda. FIGURE 25-41 Two general pathways for transposition: direct (simple) and replicative. @ The DNA is first cleaved on each side of the transposon, at the sites indicated by arrows. @ The liberated 3'-hydroxyl groups at the ends of the transposon act as nucleophiles in a direct attack on phosphodiester bonds in the target DNA. The target phosphodiester bonds are staggered (not directly across from each other) in the two DNA strands. @ The transposon is now linked to the target DNA. In direct transposition (left), replication fills in gaps at each end to complete the process. In replicative transposition (right), the entire transposon is replicated to create a cointegrate intermediate. @ The cointegrate is often resolved later, with the aid of a separate site-specific recombination system. The cleaved host DNA left behind after direct transposition is either repaired by DNA end-joining or degraded (not shown). The latter outcome can be lethal to an organism. lambda, which differ somewhat in the sequences of their constant regions. For all three types of polypeptide chain (heavy chain, and kappa and lambda light chains), diversity in the variable regions is generated by a similar mechanism. The genes for these polypeptides are divided into segments, and the genome contains clusters with multiple versions of each segment. The joining of one version of each gene segment creates a complete gene. Figure 25-42 depicts the organization of the DNA encoding the kappa light chains of human IgG and shows how a mature kappa light chain is generated. In undifferentiated cells, the coding information for this polypeptide chain is separated into three segments. The V (variable) segment encodes the first 95 amino acid residues of the variable

region, the J (joining) segment encodes the remaining 12 residues of the variable region, and the C segment encodes the constant region. The genome contains ~ 300 different V segments, 4 different J segments, and 1 C segment. As a stem cell in the bone marrow differentiates to form a mature B lymphocyte, one V segment and one J segment are brought together by a specialized recombination system (Fig. 25-42). During this programmed DNA deletion, the intervening DNA is discarded. There are about $300 \times 4 = 1,200$ possible V-J combinations. The recombination process is not as precise as the site-specific recombination described earlier, so additional variation occurs in the sequence at the V—J junction. This increases the overall variation by a factor of at least 2.5, so the cells can generate about $2.5 \times 1,200 = 3,000$ different V—J combinations. The final joining of the V—J combination to the C region is accomplished by an RNA splicing reaction after transcription, a process described in Chapter 26. The recombination mechanism for joining the V and J segments is illustrated in Figure 25-43. Just beyond each V segment and just before each J segment lie recombination signal sequences (RSS). These are bound by proteins called RAG1 and RAG2 (products of the recombination activating gene). The RAG proteins catalyze the formation of a double-strand break between

FIGURE 25-42 Recombination of the V and J gene segments of the human IgG kappa light chain. This process is designed to generate antibody diversity. At the top is shown the arrangement of IgG-coding sequences in a stem cell of the bone marrow. Recombination deletes the DNA between a particular V segment and a J segment. After transcription, the transcript is processed by RNA splicing, as described in Chapter 26; translation produces the light-chain polypeptide. The light chain can combine with any of 5,000 possible heavy chains to produce an antibody molecule. the signal sequences and the V (or J) segments to be joined. The V and J segments are then joined with the aid of a second complex of proteins. The genes for the heavy chains and the lambda light chains form by similar processes. Heavy chains have more gene segments than light chains, with more than 5,000 possible combinations. Because any heavy chain can combine with any light chain to generate an immunoglobulin, each human has at least $3,000 \times 5,000 = 1.5 \times 10^7$ possible IgGs. And additional diversity is generated by high mutation rates (of unknown mechanism) in the V sequences during B-lymphocyte differentiation. Each mature B lymphocyte produces only one type of antibody, but the range of antibodies produced by the B lymphocytes of an individual organism is clearly enormous. Did the immune system evolve in part from ancient transposons? The mechanism for generation of the double-strand breaks by RAG1 and RAG2 does mirror several reaction steps in transposition (Fig. 25—43). In addition, the deleted DNA, with its terminal RSS, has a sequence structure found in most transposons. In the test tube, RAG1 and RAG2 can associate with this transcription | 7 ees: removal of sequences between J, and C by mRNA splicing | Processed J [Vea [la] c a translation | Variable Constant region | region Primary transcript Light-chain polypeptide protein folding and assembly Light chain l = a Heavy chain Antibody ze molecule deleted DNA and insert it, transposonlike, into other DNA molecules (probably a rare reaction in B lymphocytes). Although we cannot know for certain, the properties of the immunoglobulin gene

rearrangement system suggest an intriguing origin in which the distinction between host and parasite has become blurred by evolution. SUMMARY 25.3 DNA Recombination > DNA sequences are rearranged in recombination reactions, usually in processes tightly coordinated with DNA replication or repair. > Homologous genetic recombination can take place between any two DNA molecules that share sequence homology. In bacteria, recombination serves mainly as a DNA repair process, focused on reactivating stalled or collapsed replication forks or on the general repair of double-strand breaks. In eukaryotes, recombination is essential to ensure accurate chromosomal segregation during the first meiotic cell division. It also helps to create genetic diversity in the resulting gametes.

1052 DNA Metabolism Intervening | DNA | V segment RSS

 transesterification — h I double-strand break repair via end-joining
 <—\—— V J FIGURE 25-43 Mechanism of immunoglobulin gene
 rearrangement. The RAG1 and RAG2 proteins bind to the
 recombination signal sequences (RSS) and cleave one DNA strand
 between the RSS and the V (or J) segments to be joined. The
 liberated 3' hydroxyl then acts as a nucleophile, attacking a
 phosphodiester bond in the other strand to create a double-strand
 break. The resulting hairpin bends on the V and J segments are
 cleaved, and the ends are covalently linked by a complex of
 proteins specialized for end-joining repair of double-strand breaks.
 The steps in the generation of the double-strand break catalyzed by
 RAG1 and RAG2 are chemically related to steps in transposition
 reactions. > Site-specific recombination occurs only at specific
 target sequences, and this process can also involve a Holliday
 intermediate. Recombinases cleave the DNA at specific points and
 ligate the strands to new partners. This type of recombination is
 found in virtually all cells, and its many functions include DNA
 integration and regulation of gene expression. > In virtually all
 cells, transposons use recombination to move within or between
 chromosomes. In vertebrates, a programmed recombination
 reaction related to transposition joins immunoglobulin gene
 segments to form immunoglobulin genes during B-lymphocyte
 differentiation. Key Terms Terms in bold are defined in the glossary.

Problems 1. Conclusions from the Meselson-Stahl Experiment The Meselson-Stahl experiment (see Fig. 25-2) proved that DNA undergoes semiconservative replication in *E. coli*. In the “dispersive” model of DNA replication, the parent DNA strands are cleaved into pieces of random size, then joined with pieces of newly replicated DNA to yield daughter duplexes. Explain how the results of Meselson and Stahl’s experiment ruled out such a model. 2. Heavy Isotope Analysis of DNA Replication A culture of *E. coli* growing in a medium containing ^{15}N is switched to a medium containing ^{14}N for three generations (an eightfold increase in population). What is the molar ratio of hybrid DNA (^{15}N - ^{14}N) to light DNA (^{14}N - ^{14}N) at this point? 3. Replication of the *E. coli* Chromosome The *E. coli* chromosome contains 4,639,221 bp. (a) How many turns of the double helix must be unwound during replication of the *E. coli* chromosome? (b) From the data in this chapter, how long would it take to replicate the *E. coli* chromosome at 37°C if two replication forks proceeded from the origin? Assume replication occurs at a rate of 1,000 bp/s. Under some conditions *E. coli* cells can divide every 20 min. How might this be possible? (c) In the replication of the *E. coli* chromosome, about how many Okazaki fragments would be formed? What factors guarantee that the numerous Okazaki fragments are assembled in the correct order in the new DNA? 4. Base Composition of DNAs Made from Single-Stranded Templates Predict the base composition of the total DNA synthesized by DNA polymerase on templates

provided by an equimolar mixture of the two complementary strands of bacteriophage #X174 DNA (a circular DNA molecule). The base composition of one strand is A, 24.7%; G, 24.1%; C, 18.5%; and T, 32.7%. What assumption is necessary to answer this problem?

5. DNA Replication Kornberg and his colleagues incubated soluble extracts of *E. coli* with a mixture of dATP, dTTP, dGTP, and dCTP, all labeled with ^{32}P in the α -phosphate group. After a time, the incubation mixture was treated with trichloroacetic acid, which precipitates the DNA but not the nucleotide precursors. The precipitate was collected, and the extent of precursor incorporation into DNA was determined from the amount of radioactivity present in the precipitate. (a) If any one of the four nucleotide precursors were omitted from the incubation mixture, would radioactivity be found in the precipitate? Explain. (b) Would ^{32}P be incorporated into the DNA if only dTTP were labeled? Explain.

1054 DNA Metabolism (c) Would radioactivity be found in the precipitate if ^{32}P labeled the β or γ phosphate rather than the α phosphate of the deoxyribonucleotides? Explain.

6. The Chemistry of DNA Replication All DNA polymerases synthesize new DNA strands in the $5' \rightarrow 3'$ direction. In some respects, replication of the antiparallel strands of duplex DNA would be simpler if there were also a second type of polymerase, one that synthesized DNA in the $3' \rightarrow 5'$ direction. The two types of polymerase could, in principle, coordinate DNA synthesis without the complicated mechanics required for lagging strand replication. However, no such $3' \rightarrow 5'$ -synthesizing enzyme has been found. Suggest two possible mechanisms for $3' \rightarrow 5'$ DNA synthesis. Pyrophosphate should be one product of both proposed reactions. Could one or both mechanisms be supported in a cell? Why or why not? (Hint: You may suggest the use of DNA precursors not actually present in extant cells.)

7. Activities of DNA Polymerases You are characterizing a new DNA polymerase. When the enzyme is incubated with [^{32}P]-labeled DNA and no dNTPs, you observe the release of [^{32}P]GNMPs. This release is prevented by adding unlabeled dNTPs. Explain the reactions that most likely underlie these observations. What would you expect to observe if you added pyrophosphate instead of dNTPs?

8. Leading and Lagging Strands Prepare a table that lists the names and compares the functions of the precursors, enzymes, and other proteins needed to make the leading strand versus the lagging strand during DNA replication in *E. coli*.

9. Function of DNA Ligase Some *E. coli* mutants contain defective DNA ligase. When these mutants are exposed to ^3H -labeled thymine and the DNA produced is sedimented on an alkaline sucrose density gradient, two radioactive bands appear. One corresponds to a high molecular weight fraction, the other to a low molecular weight fraction. Explain.

10. Fidelity of Replication of DNA What factors promote the fidelity of replication during synthesis of the leading strand of DNA? Would you expect the lagging strand to be made with the same fidelity? Give reasons for your answers.

11. Importance of DNA Topoisomerases in DNA Replication DNA unwinding, such as that occurring in replication, affects the superhelical density of DNA. In the absence of topoisomerases, the DNA would become overwound ahead of a replication fork as the DNA is unwound behind it. A bacterial replication fork will stall when the

superhelical density (7) of the DNA ahead of the fork reaches +0.14 (see Chapter 24). Bidirectional replication is initiated at the origin of a 6,000 bp plasmid *in vitro*, in the absence of topoisomerases. The plasmid initially has a σ of -0.06 . How many base pairs will be unwound and replicated by each replication fork before the forks stall? Assume that both forks travel at the same rate and that each includes all components necessary for elongation except topoisomerase.

12. The Ames Test In a nutrient medium that lacks histidine, a thin layer of agar containing $\sim 10^8$ *Salmonella typhimurium* histidine auxotrophs (mutant cells that require histidine to survive) produces ~ 13 colonies over a two-day incubation period at 37°C (see Fig. 25-20). How do these colonies arise in the absence of histidine? The experiment is repeated in the presence of 0.4 μg of 2-aminoanthracene. The number of colonies produced over two days exceeds 10,000. What does this indicate about 2-aminoanthracene? What can you surmise about its carcinogenicity?

13. DNA Repair Mechanisms Vertebrate and plant cells often methylate cytosine in DNA to form 5-methylcytosine (see Fig. 8-5a). In these same cells, a specialized repair system recognizes G-T mismatches and repairs them to G=C base pairs. How might this repair system be advantageous to the cell? (Explain in terms of the presence of 5-methylcytosine in the DNA.)

14. DNA Repair in People with Xeroderma Pigmentosum The condition known as xeroderma pigmentosum (XP) arises from mutations in at least seven different human genes (see Box 25-1). The deficiencies are generally in genes encoding enzymes involved in some part of the pathway for human nucleotide-excision repair. The various types of XP are denoted A through G (XPA, XPB, etc.), with a few additional variants lumped under the label XP-V. Cultures of fibroblasts from healthy individuals and from patients with XPG are irradiated with ultraviolet light. The DNA is isolated and denatured, and the resulting single-stranded DNA is characterized by analytical ultracentrifugation. (a) Samples from the normal fibroblasts show a significant reduction in the average molecular weight of the single-stranded DNA after irradiation, but samples from the XPG fibroblasts show no such reduction. Why might this be? (b) If you assume that a nucleotide-excision repair system is operative in fibroblasts, which step might be defective in the cells from the patients with XPG? Explain.

15. Holliday Intermediates How does the formation of Holliday intermediates in homologous genetic

recombination differ from their formation in site-specific recombination? 16. Cleavage of Holliday Intermediates A Holliday intermediate is formed between two homologous chromosomes, at a point between genes A and B, as shown below. The chromosomes have different alleles of the two genes (A and a, B and b). Where would the Holliday intermediate have to be cleaved (points X and/or Y) to generate a chromosome that would convey (a) an Ab genotype or (b) an ab genotype? 17. A Connection between Replication and Site-Specific Recombination Most wild strains of *Saccharomyces cerevisiae* have multiple copies of the circular plasmid 2u (named for its contour length of about 2 μ m), which has ~6,300 bp of DNA. For its replication the plasmid uses the host replication

system, under the same strict control as the host cell chromosomes, replicating only once per cell cycle. Replication of the plasmid is bidirectional, with both replication forks initiating at a single, well-defined origin. However, one replication cycle of a 2p plasmid can result in more than two copies of the plasmid, allowing amplification of the plasmid copy number (number of plasmid copies per cell) whenever plasmid segregation at cell division leaves one daughter cell with fewer than the normal complement of plasmid copies. Amplification requires a sitespecific recombination system encoded by the plasmid, which serves to invert one part of the plasmid relative to the other. Explain how a site-specific inversion event could result in amplification of the plasmid copy number. (Hint: Consider the situation when replication forks have duplicated one recombination site but not the other.)

Data Analysis Problem 18. Mutagenesis in *Escherichia coli* Many mutagenic compounds act by alkylating the bases in DNA. The alkylating agent R7000 (7-methoxy-2-nitronaphtho[2,1-b]furan) is an extremely potent mutagen. In vivo, R7000 is activated by the enzyme nitroreductase, and this more reactive form covalently attaches to DNA—primarily, but not exclusively, to G=C base pairs. In a 1996 study, Quillardet, Touati, and Hofnung explored the mechanisms by which R7000 causes mutations in *E. coli*. They compared the genotoxic activity of R7000 in two strains of *E. coli*: the wild-type (Uvr⁺) and mutants lacking uvrA activity (Uvr⁻; see Table 25-6). They first measured rates of mutagenesis. Rifampicin is an inhibitor of RNA polymerase (see Chapter 26). In its presence, cells will not grow unless certain mutations occur in the gene encoding RNA polymerase; the appearance of rifampicin-resistant colonies thus provides a useful measure of mutagenesis rates. The effects of different concentrations of R7000 were determined, with the results shown in the graph below.

R7000 (μg/mL)	Survival (%)
0	100
0.2	~95
0.4	~90
0.6	~85
0.8	~80

Data Analysis Problem 1055 (a) Why are some mutants produced even when no R7000 is present? Quillardet and colleagues also measured the survival rate of bacteria treated with different concentrations of R7000 with the following results.

R7000 (g/mL)	Survival (%)
0	100
0.2	~95
0.4	~90
0.6	~85
0.8	~80

(b) Explain how treatment with R7000 is lethal to cells. **(c)** Explain the differences in the mutagenesis curves and in the survival curves for the two

types of bacteria, Uvr⁺ and Uvr⁻, as shown in the graphs. The researchers then went on to measure the amount of R7000 covalently attached to the DNA in Uvr⁺ and Uvr⁻ E. coli. They incubated bacteria with [³H]R7000 for 10 or 70 minutes, extracted the DNA, and measured its ³H content in counts per minute (cpm) per μ g of DNA.

Strain	Time (min)	³ H in DNA (cpm/ μ g)
Uvr ⁺	10	76
Uvr ⁺	70	159
Uvr ⁻	10	69
Uvr ⁻	70	228

(d) Explain why the amount of ³H drops over time in the Uvr⁺ strain and rises over time in the Uvr⁻ strain. Quillardet and colleagues then examined the particular DNA sequence changes caused by R7000 in the Uvr⁺ and Uvr⁻ bacteria. For this, they used six different strains of E. coli, each with a different point mutation in the lacZ gene, which encodes B-galactosidase (this enzyme catalyzes the same reaction as lactase; see Fig. 14-11). Cells with any of these mutations have a nonfunctional B-galactosidase and are unable to metabolize lactose (i.e., a Lac⁻ phenotype). Each type of point mutation required a specific reverse mutation to restore lacZ gene function and Lac⁺ phenotype. By plating cells on a medium containing lactose as the sole carbon source, it was possible to select for these reverse-mutated, Lac⁺ cells. And by counting the number of Lac⁺ cells following mutagenesis of a particular strain, the researchers could measure the frequency of each type of mutation. First, they looked at the mutation spectrum in Uvr cells. The following table shows the results for the six strains, CC101 through CC106 (with the point mutation required to produce Lac⁺ cells indicated in parentheses).

1056 DNA Metabolism Number of Lac* cells (average + SD) CC101 C102 CC103 C104 C105 C106 (A=T (G=C (G=C (G=C (A=T (A=T R7000 to to to To to to (ug/mL) C=G) A=T) C=G) T=A) T=A) G=C) 0 643 119 2&1 583 241 11 0.075 24+19 3443 8+4 82+23 40414 4+2 0.15 24+4 26+2 9+5 180+71 130+50 3+2 (e) Which types of mutation show significant increases above the background rate due to treatment with R7000? Provide a plausible explanation for why some have higher frequencies than others. (f) Can all of the mutations you listed in (e) be explained as resulting from covalent attachment of R7000 to a G=C base pair? Explain your reasoning. (g) Figure 25-27b shows how methylation of guanine residues can lead to a G=C to A=T mutation. Using a similar pathway, show how a G-R7000 adduct could lead to the G=C to A=T or T=A mutations shown above. Which base pairs with the G-R7000 adduct? The results for the Uvr* bacteria are shown in the table below. Number of Lac* cells (average + SD) CC101 CC102 CC103 CC104 CC105 CC106 (A=T (G=C (G=C (G=C (A=T (A=T R7000 to to to to to to (ug/mL) C=G) A=T) C=G) T=A) T=A) G=C) 0 2+2 1049 3+3 4+2 6+1 0521 1 7+6 21+9 843 23415 138+1 LEL 5 4+3 15+7 22+2 68 +25 67414 1+1 (h) Do these results show that all mutation types are repaired with equal fidelity? Provide a plausible explanation for your answer. Reference Quillardet, P., Touati, E., & Hofnung, M. RNA Metabolism 26.1 DNA-Dependent Synthesis of RNA 1058 26.2 RNA Processing 1069 26.3 RNA-Dependent Synthesis of RNA and DNA 1085

involves production of an RNA molecule transcribed from a DNA template. Strands of RNA and DNA may seem quite similar at first glance, differing only in that RNA has a hydroxyl group at the 2' position of the aldopentose, and uracil instead of thymine. However, unlike DNA, most RNAs carry out their functions as single strands, strands that fold back on themselves and have the potential for much greater structural diversity than DNA (Chapter 8). RNA is thus suited to a variety of cellular functions. RNA is the only macromolecule known to have a role both in the storage and transmission of information and in catalysis, which has led to much speculation about its possible role as an essential chemical intermediate in the development of life on this planet. The discovery of catalytic RNAs, or ribozymes, has changed the very definition of an enzyme, extending it beyond the domain of proteins. Proteins nevertheless remain essential to RNA and its functions. In the modern cell, all nucleic acids, including RNAs, are complexed with proteins. Some of these complexes are quite elaborate, and RNA can assume both structural and catalytic roles within complicated biochemical machines. All RNA molecules except the RNA genomes of certain viruses are derived from information permanently stored in DNA. During transcription, an enzyme system converts the genetic information in a segment of double-stranded DNA into an RNA strand with a base sequence complementary to one of the DNA strands. Three major kinds of RNA are produced. Messenger RNAs (mRNAs) encode the amino acid sequence of one or more polypeptides specified by a gene or set of genes. Transfer RNAs (tRNAs) read the information encoded in the mRNA and transfer the appropriate amino acid to a growing polypeptide chain during protein synthesis. Ribosomal RNAs (rRNAs) are constituents of ribosomes, the intricate cellular machines that synthesize proteins. Many additional, specialized RNAs have regulatory or catalytic functions or are precursors to the three main classes of RNA. These special-function RNAs are no longer thought of as minor species in the catalog of cellular RNAs. In vertebrates, RNAs that do not fit into one of the classical categories (mRNA, tRNA, rRNA) seem to vastly outnumber those that do. During replication

the entire chromosome is usually copied, but transcription is more selective. Only particular genes or groups of genes are transcribed at any one time, and some portions of the DNA genome are never transcribed. The cell restricts the expression of genetic information to the formation of gene products needed at any particular moment. Specific regulatory sequences mark the beginning and end of the DNA segments to be transcribed and designate which strand in duplex DNA is to be used as the template. The transcript itself may interact with other RNA molecules as part of the overall regulatory program. The regulation of transcription is described in detail in Chapter 28. The sum of all the RNA molecules produced in a cell under a given set of conditions is called the cellular transcriptome. Given the relatively small fraction of the human genome devoted to protein-encoding genes, we might expect that only a small part of the human genome is transcribed. This is not the case. Modern microarray analysis of transcription patterns has revealed that much of the genome of humans and other mammals is transcribed into RNA. The products are predominantly not mRNAs, tRNAs, or rRNAs, but rather special-function RNAs, a host of which are being discovered. Many of these seem to be involved in regulation of gene expression; however, the rapid pace of discovery has forced the realization that we do not yet know what many of these RNAs do. In this chapter we examine the synthesis of RNA on a DNA template and the postsynthetic processing and turnover of RNA molecules. In doing so, we encounter many of the specialized functions of RNA, including 1057

1058 RNA Metabolism catalytic functions. Interestingly, the substrates for RNA enzymes are often other RNA molecules. We also describe systems in which RNA is the template and DNA the product, rather than vice versa. The information pathways thus come full circle, and reveal that template-dependent nucleic acid synthesis has standard rules, regardless of the nature of template or product (RNA or DNA). This examination of the biological interconversion of DNA and RNA as information carriers leads to a discussion of the evolutionary origin of biological information.

26.1 DNA-Dependent Synthesis of RNA

Our discussion of RNA synthesis begins with a comparison between transcription and DNA replication (Chapter 25). Transcription resembles replication in its fundamental chemical mechanism, its polarity (direction of synthesis), and its use of a template. And like replication, transcription has initiation, elongation, and termination phases—though in the literature on transcription, initiation is further divided into discrete (a) Template & DNA 3' strand Growing RNA, strand “n UL g “ RNA polymerase MECHANISM FIGURE 26-1

Transcription by RNA polymerase in *E. coli*.

For synthesis of an RNA strand complementary to one of two DNA strands in a double helix, the DNA is transiently unwound. (a) Catalytic mechanism of RNA synthesis by RNA polymerase. Note that this is essentially the same mechanism used by DNA polymerases (see Fig. 25-5a). The reaction involves two Mg^{2+} ions, coordinated to the phosphate groups of the incoming nucleoside triphosphates (NTPs) and to three Asp residues, which are highly conserved in the RNA polymerases of all species. One Mg^{2+} ion facilitates attack by the 3'-hydroxyl group on the α phosphate of the NTP; the other Mg^{2+} ion facilitates displacement of the pyrophosphate, and both metal ions stabilize the pentacoordinate transition state. (b) About 17 bp of DNA are unwound at any given time. RNA polymerase and the transcription bubble move from left to right along the phases of DNA binding and initiation of RNA synthesis. Transcription differs from replication in that it does not require a primer and, generally, involves only limited segments of a DNA molecule. Additionally, within transcribed segments, only one DNA strand serves as a template for a particular RNA molecule.

RNA Is Synthesized by RNA Polymerases

The discovery of DNA polymerase and its dependence on a DNA template spurred a search for an enzyme that

synthesizes RNA complementary to a DNA strand. By 1960, four research groups had independently detected an enzyme in cellular extracts that could form an RNA polymer from ribonucleoside 5'-triphosphates. Subsequent work on the purified *Escherichia coli* RNA polymerase helped to define the fundamental properties of transcription (Fig. 26-1). DNA-dependent RNA polymerase requires, in addition to a DNA template, all four ribonucleoside 5'-triphosphates (ATP, GTP, UTP, and CTP) as precursors of the nucleotide units of RNA, as well as Mg^{2+} . The protein also binds one Zn^{2+} . The chemistry and mechanism of RNA synthesis closely resemble those of DNA synthesis.

(b) Direction of transcription DNA strand Template Nontemplate DNA § ADA, duplex 3' # " . x BS 5 md Or, P 3" RNA (c) Positive supercoils Negative supercoils Direction of transcription VN 3/ 'Ae À = ~ NTP entry RNA exit TM channel DNA as shown, facilitating RNA synthesis. The DNA is unwound ahead and rewound behind as RNA is transcribed. As the DNA is rewound, the RNA-DNA hybrid is displaced and the RNA strand is extruded. (c) Movement of an RNA polymerase along DNA tends to create positive supercoils (overwound DNA) ahead of the transcription bubble and negative supercoils (underwound DNA) behind it. The RNA polymerase is in close contact with the DNA ahead of the transcription bubble as well as with the separated DNA strands and the RNA within and immediately behind the bubble. A channel in the protein funnels new NTPs to the polymerase active site. The polymerase footprint encompasses about 35 bp of DNA during elongation.

6) CGCTATAGCGTITT@G') (3') GCGA TAT ECGCAAA(S')
DNA nontemplate (coding) strand DNA template strand (5')
CGCUAUAGC GUUU(3') RNA transcript resemble those used by
DNA polymerases (see Fig. 25-ba). RNA polymerase elongates an
RNA strand by adding ribonucleotide units to the 3'-hydroxyl end,
building RNA in the 5'—3' direction. The 3'-hydroxyl group acts as
anucleophile, attacking the a phosphate of the incoming
ribonucleoside triphosphate (Fig. 26—1a) and releasing
pyrophosphate. The overall reaction is (NMP), + NTP —> (NMP)
RNA Lengthened RNA + PP; RNA polymerase requires DNA for
activity and is most active when bound to a double-stranded DNA.
As noted above, only one of the two DNA strands serves as a
template. The template DNA strand is copied in the 3'—> 5'
direction (antiparallel to the new RNA strand), just as in DNA
replication. Each nucleotide in the newly formed RNA is selected by
Watson-Crick base-pairing interactions: U residues are inserted in
the RNA to pair with A residues in the DNA template, G residues
are inserted to pair with C residues, and so on. Base-pair geometry
(see Fig. 25-6) may also play a role in base selection. Unlike DNA
polymerase, RNA polymerase does not require a primer to initiate
synthesis. Initiation occurs when RNA polymerase binds at specific
DNA sequences called promoters (described below). The 5'-
triphosphate group of the first residue in a nascent (newly formed)
RNA molecule is not cleaved to release PP;, but instead remains
intact throughout the transcription process. During the elongation
phase of transcription, the growing end of the new RNA strand
base-pairs temporarily with the DNA template to form a short
hybrid RNA-DNA double helix, estimated to be 8 bp long (Fig. 26—
1b). The RNA in this hybrid duplex “peels off” shortly after its
formation, and the DNA duplex re-forms. DNA 3

FIGURE 26-3
Organization of coding information in the adenovirus genome. The
genetic information of the adenovirus genome (a conveniently
simple example) is encoded by a double-stranded DNA molecule of
36,000 bp, both strands of which encode proteins. The information
for most proteins is encoded by (that is, identical to) the top strand
—by convention, the strand oriented 5' to 3' from left to right. The
bottom strand acts as template for these transcripts. However, a few
proteins are en3.6X10°bo < = —p ny = > 26.1 DNA-Dependent
Synthesisof RNA 1059

FIGURE 26-2 Template and nontemplate

(coding) DNA strands. The two complementary strands of DNA are defined by their function in transcription. The RNA transcript is synthesized on the template strand and is identical in sequence (with U in place of T) to the nontemplate strand, or coding strand. To enable RNA polymerase to synthesize an RNA strand complementary to one of the DNA strands, the DNA duplex must unwind over a short distance, forming a transcription “bubble.” During transcription, the *Æ. colt* RNA polymerase generally keeps about 17 bp unwound. The 8 bp RNA-DNA hybrid occurs in this unwound region. Elongation of a transcript by *E. coli* RNA polymerase proceeds at a rate of 50 to 90 nucleotides/s. Because DNA is a helix, movement of a transcription bubble requires considerable strand rotation of the nucleic acid molecules. DNA strand rotation is restricted in most DNAs by DNA-binding proteins and other structural barriers. As a result, a moving RNA polymerase generates waves of positive supercoils ahead of the transcription bubble and negative supercoils behind (Fig. 26-1c). This has been observed both in vitro and in vivo *Gn* bacteria). In the cell, the topological problems caused by transcription are relieved through the action of topoisomerases (Chapter 24). **KEY CONVENTION:** The two complementary DNA strands have different roles in transcription. The strand that serves as template for RNA synthesis is called the template strand. The DNA strand complementary to the template, the nontemplate strand, or coding strand, is identical in base sequence to the RNA transcribed from the gene, with U in the RNA in place of T in the DNA (Fig. 26-2). The coding strand for a particular gene may be located in either strand of a given chromosome (as shown in Fig. 26-3 for a virus). By convention, the regulatory sequences that control transcription (described later in this chapter) are designated by the sequences in the coding strand. $E\ asl\ 3' \ 5' \text{ — } = > = >$ RNA transcripts coded by the bottom strand, which is transcribed in the opposite direction (and uses the top strand as template). Synthesis of mRNAs in adenovirus is actually much more complex than shown here. Many of the mRNAs derived using the upper strand as template are initially synthesized as a single, long transcript (25,000 nucleotides), which is then extensively processed to produce the separate mRNAs. Adenovirus causes upper respiratory tract infections in some vertebrates.

1060 RNA Metabolism FIGURE 26-4 Structure of the RNA polymerase holoenzyme of the bacterium *Thermus aquaticus*. (Derived from PDB ID 1HQM) The overall structure of this enzyme is very similar to that of the *E. coli* RNA polymerase; no DNA or RNA is shown here. The several subunits of the bacterial RNA polymerase give the enzyme the shape of a crab claw. The pincers are formed from the large β and β' subunits. The subunits are shown in the same colors in the schematic and the ribbon structure. The DNA-dependent RNA polymerase of *E. coli* is a large, complex enzyme with five core subunits (α , β , β' , ω , and σ , 390,000) and a sixth subunit, one of a group designated σ , with variants designated by size (molecular weight). The σ subunit binds transiently to the core and directs the enzyme to specific binding sites on the DNA (described below). These six subunits constitute the RNA polymerase holoenzyme (Fig. 26-4). The RNA polymerase holoenzyme of *E. coli* thus exists in several forms, depending on the type of a subunit. The most common subunit is σ^{70} (M, 70,000), and the upcoming discussion focuses on the corresponding RNA polymerase holoenzyme. RNA polymerases lack a separate proofreading 3'—5' exonuclease active site (such as that of many DNA polymerases), and the error rate for transcription is higher than that for chromosomal DNA replication—approximately one error for every 10^4 to 10^6 ribonucleotides incorporated into RNA. Because many copies of an RNA are generally produced from a single gene and all RNAs are eventually degraded and replaced, a mistake in an RNA molecule is of less consequence to the cell than a mistake in the permanent information stored in DNA. Many RNA polymerases, including bacterial RNA polymerase and the eukaryotic RNA polymerase II (discussed below), do pause when a mispaired base is added during transcription, and they can remove mismatched nucleotides from the 3' end of a transcript by direct reversal of the polymerase reaction. But we do not yet know whether this activity is a true proofreading function and to what extent it may contribute to the fidelity of transcription.

RNA Synthesis Begins at Promoters Initiation of RNA synthesis at random points in a DNA molecule would be an extraordinarily wasteful process. Instead, an RNA polymerase binds to specific sequences in the DNA called promoters, which direct the transcription of adjacent segments of DNA (genes). The sequences where RNA

polymerases bind can be quite variable, and much research has focused on identifying the particular sequences that are critical to promoter function. In *E. coli*, RNA polymerase binding occurs within a region stretching from about 70 bp before the transcription start site to about 30 bp beyond it. By convention, the DNA base pairs that correspond to the beginning of an RNA molecule are given positive numbers, and those preceding the RNA start site are given negative numbers. The promoter region thus extends between positions -70 and $+30$. Analyses and comparisons of the most common class of bacterial promoters (those recognized by an RNA polymerase holoenzyme containing σ) have revealed similarities in two short sequences centered about positions -10 and -35 (Fig. 26-5). These sequences are important interaction sites for the σ subunit. Although the sequences are not identical for all bacterial promoters in this class, certain nucleotides that are particularly common at each position form a consensus sequence (recall the *E. coli* *oriC* consensus sequence; see Fig. 25-10). The consensus sequence at the -10 region is (5')TATAAT(3'); the consensus sequence at the -35 region is (5')TTGACA(3'). A third AT-rich recognition element, called the UP (upstream promoter) element, occurs between positions -40 and -60 in the promoters of certain highly expressed genes. The UP element is bound by the α subunit of RNA polymerase. The efficiency with which an RNA polymerase containing σ^{TM} binds to a promoter and initiates transcription is determined in large measure by these sequences, the spacing between them, and their distance from the transcription start site. Many independent lines of evidence attest to the functional importance of the sequences in the -35 and -10 regions. Mutations that affect the function of a given promoter often involve a base pair in these regions. Variations in the consensus sequence also affect the efficiency of RNA polymerase binding and transcription initiation. A change in only one base pair can decrease the rate of binding by several orders of magnitude. The promoter sequence thus establishes a basal level of expression that can vary greatly from one *E. coli* gene to the next. A method that provides information about the interaction between RNA polymerase and promoters is illustrated in Box 26-1. The pathway of transcription initiation and the fate of the σ subunit are becoming much better defined (Fig. 26-6). The pathway consists of two major parts, binding and initiation, each with multiple steps. First, the

polymerase, directed by its bound σ factor, binds to the promoter. A closed complex (in which the bound DNA is intact) and an open complex (in which the bound DNA is intact and partially unwound near the -10 sequence) form in succession. Second, transcription

 coli promoters recognized by an RNA polymerase holoenzyme
 containing σ^{70} . Sequences of the nontemplate strand are shown,
 read in the 5' $\rightarrow$ 3' direction, as is the convention for
 representations of this kind. The sequences differ from one
 promoter to the next, but comparisons of many promoters reveal
 similarities, particularly in the -10 and -35 regions. The sequence
 element UP, not present in all E. coli promoters, is shown in the P1
 promoter for the highly expressed rRNA is initiated within the
 complex, leading to a conformational change that converts the
 complex to the elongation form, followed by movement of the
 transcription complex away from the promoter (promoter
 clearance). Any of these steps can be affected by the specific
 makeup of the promoter sequences. The σ subunit dissociates
 stochastically (at random) as the polymerase enters the elongation
 phase of transcription. The protein NusA (M, 54,430) binds to the
 elongating RNA polymerase, competitively with the σ subunit. Once
 transcription is complete, NusA dissociates from the enzyme, the
 RNA polymerase dissociates from the DNA, and a σ factor (σ^{70} or
 another) can again bind to the enzyme to initiate transcription. E.
 coli has other classes of promoters, bound by RNA polymerase
 holoenzymes with different σ subunits (Table 26-1). An example is
 the promoters of the heat shock genes. The products of this set of
 genes are made at higher levels when the cell has received an
 insult, such as a sudden increase in temperature. RNA polymerase
 binds to the promoters of these genes only when σ^{70} is replaced with
 the σ^{32} (M, 32,000) subunit, which is specific for the heat shock
 promoters (see Fig. 28-3). By using different σ subunits, the cell can
 coordinate the expression of sets of genes, permitting major changes
 in cell physiology. Which sets of genes are expressed is determined
 by the availability of the various σ subunits, which is determined by
 several factors: regulated rates of synthesis and degradation,
 postsynthetic modifications that switch individual σ subunits
 between active TACTGT gene *rrnB*. UP elements, generally
 occurring in the region between -40 and -60 , strongly stimulate
 transcription at the promoters that contain them. The UP element in

the *rrnB* P1 promoter encompasses the region between —38 and —59. The consensus sequence for *E. coli* promoters recognized by σ^{70} is shown second from the top. Spacer regions contain slightly variable numbers of nucleotides (N). Only the first nucleotide coding the RNA transcript (at position +1) is shown. and inactive forms, and a specialized class of anti- σ proteins, each type binding to and sequestering a particular σ subunit (rendering it unavailable for transcription initiation). Transcription Is Regulated at Several Levels Requirements for any gene product vary with cellular conditions or developmental stage, and transcription of each gene is carefully regulated to form gene products only in the proportions needed. Regulation can occur at any step in transcription, including elongation and termination. However, much of the regulation is directed at the polymerase binding and transcription initiation steps outlined in Figure 26-6. Differences in promoter sequences are just one of several levels of control. The binding of proteins to sequences both near to and distant from the promoter can also affect levels of gene expression. Protein binding can activate transcription by facilitating either RNA polymerase binding or steps further along in the initiation process, or it can repress transcription by blocking the activity of the polymerase. In *E. coli*, one protein that activates transcription is the cAMP receptor protein (CRP), which increases the transcription of genes coding for enzymes that metabolize sugars other than glucose when cells are grown in the absence of glucose. Repressors are proteins that block the synthesis of RNA at specific genes. In the case of the Lac repressor (Chapter 28), transcription of the genes for the enzymes of lactose metabolism is blocked when lactose is unavailable.

1062 RNA Metabolism BOX 26-1 faite RNA Polymerase

Leaves Its Footprint on a Promoter Footprinting, a technique derived from principles used in DNA sequencing, identifies the DNA sequences bound by a particular protein. Researchers isolate a DNA fragment thought to contain sequences recognized by a DNA-binding protein and radiolabel one end of one strand (Fig. 1). They then use chemical or enzymatic reagents to introduce random breaks in the DNA fragment (averaging about one per molecule). Solution of identical DNA fragments radioactively labeled * at one end of one strand. 3 DNase | (+) (=) Treat with DNase under conditions in which each strand is cut once (on average). No cuts are made in the area where RNA polymerase has bound. = — DNase cut Ss Separation of the labeled cleavage products (broken fragments of various lengths) by high-resolution electrophoresis produces a ladder of radioactive bands. In a separate tube, the cleavage procedure is repeated on copies of the same DNA fragment in the presence of the DNA-binding protein. The researchers then subject the two sets of cleavage products to electrophoresis and compare them side by side. A gap (“footprint”) in the series of radioactive bands derived from the DNA-protein sample, attributable to protection of the DNA by the bound protein, identifies the sequences that the protein binds. The precise location of the proteinbinding site can be determined by directly sequencing (see Fig. 8-34) copies of the same DNA fragment and including the sequencing lanes (not shown here) on the same gel with the footprint. Figure 2 shows footprinting results for the binding of RNA polymerase to a DNA fragment containing a promoter. FIGURE 26-6 Transcription initiation and elongation by *E. coli* RNA

polymerase. Initiation of transcription requires several steps generally divided into two phases, binding and initiation. In the binding phase, the initial interaction of the RNA polymerase with the promoter leads to formation of a closed complex, in which the promoter DNA is stably bound but not unwound. A 12 to 15 bp region of DNA—from within the —10 region to position +2 or +3—is then unwound to form an open complex. Additional

intermediates (not shown) have been detected in the pathways leading to the closed and open complexes, along with several

Transcription is the first step in the complicated and energy-intensive pathway of protein synthesis, so much of the regulation of protein levels in both bacterial and eukaryotic cells is directed at transcription, particularly its early stages. In Chapter 28 we describe many mechanisms by which this regulation is

accomplished. Specific Sequences Signal Termination of RNA

Synthesis RNA synthesis is processive; that is, the RNA polymerase

core binds to the DNA promoter. Transcription bubble forms. Closed

complex Open complex A 2D < (3) Transcription is initiated.

Promoter clearance is followed by elongation. changes in protein

conformation. The initiation phase encompasses transcription

initiation and promoter clearance (steps @ through @ here). Once

elongation commences, the o subunit is released and it is replaced

by the protein NusA. The polymerase leaves the promoter and

becomes committed to elongation of the RNA (step @). When

transcription is complete, the RNA is released, the NusA protein

dissociates, and the RNA polymerase dissociates from the DNA (step

@). Another ø subunit binds to the RNA polymerase and the process

begins again. into a growing RNA molecule before dissociating (p.

1014). This is necessary because, if an RNA polymerase released an

RNA transcript prematurely, it could not resume synthesis of the

same RNA but instead would have to start again. However, an

encounter with certain DNA sequences results in a pause in RNA

synthesis, and at some of these sequences transcription is

terminated. Our focus here is again on the well-studied systems in bacteria. *E. coli* has at least two classes of termination signals: one class relies on a protein factor called ρ (rho) and the other is ρ -independent.

Nucleic Acids Res. 28, 3500. Note: σ factors are widely distributed
in bacteria; the number varies from a single σ factor in Mycoplasma
genitalium to 63 distinct σ factors in Streptomyces coelicolor.
*Approximate number of each σ subunit per cell and the fraction of
RNA polymerase holoenzyme complexed with each σ subunit
during exponential growth. The numbers change as growth
conditions change. The fraction of RNA polymerase complexed with
each σ subunit reflects both the amount of the particular subunit
and its affinity for the enzyme. Most p-independent terminators
have two distinguishing features. The first is a region that produces
an RNA transcript with self-complementary sequences, permitting
the formation of a hairpin structure (see Fig. 8-19a) centered 15 to
20 nucleotides before the projected end of the RNA strand. The
second feature is a highly conserved string of three A residues in the
template strand that are transcribed into U residues near the 3' end
of the hairpin. When a polymerase arrives at a termination site with
this structure, it pauses (Fig. 26—7a). Formation of the hairpin
structure in the RNA disrupts several A=U base pairs in the RNA-
DNA hybrid segment and may disrupt important interactions
between RNA and the RNA polymerase, facilitating dissociation of
the transcript. The p-dependent terminators lack the sequence of
repeated A residues in the template strand but usually include a CA-
rich sequence called a rut (rho utilization) element. The p protein
associates with the RNA at specific binding sites and migrates in the
5'—3' direction until it reaches the transcription complex that is
paused at a termination site (Fig. 26-7b). Here it contributes to
release of the RNA transcript. The p protein has an ATP-dependent
RNA-DNA helicase activity that promotes translocation of the
protein along the RNA, and ATP is hydrolyzed by p protein during
the termination process. The detailed mechanism by which the

protein promotes the release of the RNA transcript is not known.

Eukaryotic Cells Have Three Kinds of Nuclear RNA Polymerases

The transcriptional machinery in the nucleus of a eukaryotic cell is much more complex than that in bacteria. Eukaryotes have three RNA polymerases, designated I, II, and III, which are distinct complexes but have certain subunits in common. Each polymerase has a specific function and is recruited to a specific promoter sequence. RNA polymerase I (Pol I) is responsible for the synthesis of only one type of RNA, a transcript called preribosomal RNA (or pre-rRNA), which contains the precursor for the 18S, 5.8S, and 28S rRNAs (see Fig. 26-24). Pol I promoters differ greatly in sequence from one species to another. The principal function of RNA polymerase II (Pol II) is synthesis of mRNAs and some specialized RNAs. This enzyme can recognize thousands of promoters that vary greatly in sequence. Some Pol II promoters have a few sequence features in common, including a TATA box (eukaryotic consensus sequence TATA(A/T)A(A/T) (A/G)) near base pair —30 and an Inr sequence (initiator) near the RNA start site at +1 (Fig. 26-8). However, such promoters are in the minority, and Pol II operates at many promoters that lack these features. RNA polymerase III (Pol III) makes tRNAs, the 5S rRNA, and some other small specialized RNAs. The promoters recognized by Pol III are well characterized. Interestingly, some of the sequences required for the regulated initiation of transcription by Pol III are located within the gene itself, whereas others are in more conventional locations upstream of the RNA start site (Chapter 28).

RNA Polymerase II Requires Many Other Protein Factors for Its Activity

RNA polymerase II is central to eukaryotic gene expression and has been studied extensively. Although this polymerase is strikingly more complex than its bacterial counterpart, the complexity masks a remarkable conservation of structure, function, and mechanism. Pol II isolated from yeast is a huge enzyme with 12 subunits. The largest subunit (RBP1) exhibits a high degree of homology to the B' subunit of bacterial RNA polymerase.

(a) p-independent termination RNA polymerase - = = `

h RNA synthesis encounters a terminator sequence. An RNA hairpin is formed at a palindromic sequence, reducing the length of the RNA-DNA hybrid. 5 The mRNA is released. FIGURE 26-7

Termination of transcription in *E. coli*. (a) p-Independent termination. RNA polymerase pauses at a variety of DNA sequences, some of which are terminators. One of two outcomes is then possible: the polymerase bypasses the site and continues on its way, or the complex undergoes a conformational change (isomerization). In the latter case, intramolecular pairing of complementary sequences in the newly formed RNA transcript may form a hairpin that disrupts the RNA-DNA hybrid or the interactions between RNA and polymerase, or 5! Various regulatory sequences FIGURE 26-8

Some common sequences in promoters recognized by eukaryotic RNA polymerase II. The TATA box is the major assembly point for the proteins of the preinitiation complexes of Pol II. The DNA is unwound at the initiator sequence (Inr), and the transcription start site is usually within or very near this sequence. In the Inr consensus sequence shown here, N represents any nucleotide; Y, a pyrimidine nucleotide. Many additional sequences serve as binding sites for a wide variety of proteins that affect the activity of Pol II. These sequences are important in regulating Pol II promoters and differ greatly in type and number, and TATA box 26.1 DNA-

Dependent Synthesis of RNA 1065 (b) p-dependent termination The p helicase binds to a rut site. rut site p helicase ATP ADP + P, The p helicase migrates along the mRNA to the elongating RNA polymerase. The p helicase separates the mRNA from the DNA template. both, resulting in isomerization. An A = U hybrid region at the 3' end of the new transcript is relatively unstable, and the RNA dissociates from the complex completely, leading to termination. This is the usual outcome at terminators. At other pause sites, the complex may escape after the isomerization step to continue RNA synthesis. (b) p-Dependent termination. RNAs that include a rut site (purple) recruit the p helicase. The p helicase migrates along the mRNA in the 5'—3' direction and separates it from the polymerase. gal 3' Inr in general the eukaryotic promoter is much more complex than suggested here (see Fig. 15-25). Many of the sequences are located within a few hundred base pairs of the TATA box on the 5' side; others may be thousands of base pairs away. The sequence

elements summarized here are more variable among the Pol II promoters of eukaryotes than among the *E. coli* promoters (see Fig. 26-5). The majority of Pol II promoters lack a TATA box or a consensus Inr element or both. Additional sequences around the TATA box and downstream (to the right as drawn) of Inr may be recognized by one or more transcription factors.

1066 RNA Metabolism WILP Proteins Required for Initiation of Transcription at the RNA Polymerase II (Pol II) Promoters of Eukaryotes

Transcription Number of protein subunits	Subunit(s)	M, Function(s)
12	10,000—220,000	Initiation Pol II
1	38,000	Catalyzes RNA synthesis TBP (TATA-binding protein)
3	12,000, 19,000, 35,000	Specifically recognizes the TATA box TFIIA
2	34,000, 57,000	Stabilizes binding of TFIIB and TBP to the promoter TFIIB
2	34,000, 57,000	Binds to TBP; recruits Pol I-TFUF complex TFIIE
2	30,000, 74,000	Recruits TFIIF; has ATPase and helicase activities TFIIF
12	35,000-89,000	Binds tightly to Pol II; binds to TFIIB and prevents binding of Pol II to nonspecific DNA sequences TFIIH
1	80,000	Unwinds DNA at promoter (helicase activity); phosphorylates Pol II (within the CTD); recruits nucleotide-excision repair proteins Elongation* ELL
2	43,000, 124,000	pTEFb
1	38,000	Phosphorylates Pol II (within the CTD) SII (TFIIS)
3	15,000, 18,000, 110,000	Elongin (SID)

*The function of all elongation factors is to suppress the pausing or arrest of transcription by the Pol II-TFIIF complex. 'Name derived from eleven-nineteen Jysine-rich leukemia. The gene for ELL is the site of chromosomal recombination events frequently associated with acute myeloid leukemia. Another subunit (RBP2) is structurally similar to the bacterial B subunit, and two others (RBP3 and RBP11) show some structural homology to the two bacterial α subunits. Pol II must function with genomes that are more complex and with DNA molecules more elaborately packaged than in bacteria. The need for proteinprotein contacts with the numerous other protein factors required to navigate this labyrinth accounts in large measure for the added complexity of the eukaryotic polymerase. The largest subunit of Pol II (RBP1) also has an unusual feature, a long carboxyl-terminal tail consisting of many repeats of a consensus heptad amino acid sequence -YSPSPS-. There are 27 repeats in the yeast enzyme (18 exactly matching the consensus) and 52 (21 exact) in the mouse and human enzymes. This carboxyl-terminal domain (CTD) is separated from the main body of the enzyme by an inherently unstructured linker sequence. The CTD has many important roles in Pol II function, as outlined below. RNA polymerase II requires an array of other proteins, called transcription factors, in order to form the active transcription complex. The general transcription factors required at every Pol II

promoter (factors usually designated TFII with an additional identifier) are highly conserved in all eukaryotes (Table 26-2). The process of transcription by Pol II can be described in terms of several phases—assembly, initiation, elongation, termination—each associated with characteristic proteins (Fig. 26-9). The step-by-step pathway described below leads to active transcription *in vitro*. In the cell, many of the proteins may be present in larger, preassembled complexes, simplifying the pathways for assembly on promoters. As you read about this process, consult Figure 26-9 and Table 26-2 to help keep track of the many participants.

FIGURE 26-9 Transcription at RNA polymerase II promoters. (a) The sequential assembly of TBP (often with TFIIA), TFIIB, TFIIF plus Pol II, TFIIIE, and TFIIF results in a closed complex. Within the complex, the DNA is unwound at the Inr region by the helicase activity of TFIIF and perhaps of TFIIIE, creating an open complex. The carboxyl-terminal domain of the largest Pol II subunit is phosphorylated by TFIIF, and the polymerase then escapes the promoter and begins transcription. Elongation is accompanied by the release of many transcription factors and is also enhanced by elongation factors (see Table 26-2). After termination, Pol II is released, dephosphorylated, and recycled. (b) Human TBP bound to DNA. The DNA is bent in this complex, opening the minor groove to allow specific hydrogen-bonding between protein and DNA (PDB ID 1TGH). (c) A cutaway view of transcription elongation promoted by the Pol II core enzyme.

1068 RNA Metabolism Assembly of RNA Polymerase and Transcription Factors at a Promoter The formation of a closed complex begins when the TATA-binding protein (TBP) binds to the TATA box (Figs 26-9a, step @, and 26-9b). At promoters lacking a TATA box, TBP arrives as part of a multisubunit complex called TFIID (not shown in Fig. 26-9). The sequence elements that direct the binding of TFIID at TATA-less promoters are poorly understood. TBP is bound in turn by the transcription factor TFIIB, which also binds to DNA on either side of TBP. TFIIB binds, and along with TFIID helps to stabilize the TBP-DNA complex. TFIIB provides an important link to DNA polymerase II, and the TFIIB-TBP complex is next bound by another complex consisting of TFIIF and Pol II. TFIIF helps target Pol II to its promoters, both by interacting with TFIIB and by reducing the binding of the polymerase to nonspecific sites on the DNA. Finally, TFIIE and TFIIH bind to create the closed complex. TFIIH has multiple subunits and includes a DNA helicase activity that promotes the unwinding of DNA near the RNA start site (a process requiring the hydrolysis of ATP), thereby creating an open complex (Fig. 26—9a, step @). Counting all the subunits of the various essential factors (excluding TFIIA and some subunits of TFIID), this minimal active assembly has more than 30 polypeptides. Structural studies by Roger Kornberg and his collaborators have provided a more detailed look at the core structure of RNA polymerase II during elongation (Fig. 26-9c). RNA Strand Initiation and Promoter Clearance TFIIH has an additional function during the initiation phase. A kinase activity in one of its subunits phosphorylates Pol II at many places in the CTD (Fig. 26—9a). Several other protein kinases, including CDK9 (cyclin-dependent kinase 9), which is part of the complex pTEFb (positive transcription elongation factor b), also phosphorylate the CTD, primarily on the Ser residues of the CTD repeat sequence. This causes a conformational change in the overall complex, initiating transcription. Phosphorylation of the CTD is also important during the subsequent elongation phase, with the phosphorylation state of the CTD changing as transcription proceeds. The changes affect the interactions between the transcription complex and other proteins and enzymes, such that different sets of proteins are bound at initiation than at later stages. Some of these proteins are involved in processing the transcript (as described below). During synthesis of

the initial 60 to 70 nucleotides of RNA, first TFUE and then TFIIF is released, and Pol II enters the elongation phase of transcription. Elongation, Termination, and Release TFIIF remains associated with Pol II throughout elongation. During this stage, the activity of the polymerase is greatly enhanced by proteins called elongation factors (Table 26-2). The elongation factors, some bound to the phosphorylated CTD, suppress pausing during transcription and also coordinate interactions between protein complexes involved in the posttranscriptional processing of mRNAs. Once the RNA transcript is completed, transcription is terminated. Pol II is dephosphorylated and recycled, ready to initiate another transcript (Fig. 26-9a, steps © to ©). Regulation of RNA Polymerase II Activity Regulation of transcription at Pol II promoters is quite elaborate. It involves the interaction of a wide variety of other proteins with the preinitiation complex. Some of these regulatory proteins interact with transcription factors, others with Pol II itself. The regulation of transcription is described in more detail in Chapter 28.

Diverse Functions of TFIIF In eukaryotes, the repair of damaged DNA (see Table 25-5) is more efficient within genes that are actively being transcribed than for other damaged DNA, and the template strand is repaired somewhat more efficiently than the nontemplate strand. These remarkable observations are explained by the alternative roles of the TFIIF subunits. Not only does TFIIF participate in formation of the closed complex during assembly of a transcription complex (as described above), but some of its subunits are also essential components of the separate nucleotide-excision repair complex (see Fig. 25-25). When Pol II transcription halts at the site of a DNA lesion, TFIIF can interact with the lesion and recruit the entire nucleotide-excision repair complex. Genetic loss of certain TFIIF subunits can produce human diseases. Some examples are xeroderma pigmentosum (see Box 25-1) and Cockayne syndrome, which is characterized by arrested growth, photosensitivity, and neurological disorders.

E DNA-Dependent RNA Polymerase Undergoes Selective Inhibition The elongation of RNA strands by RNA polymerase in both bacteria and eukaryotes is inhibited by the antibiotic actinomycin D (Fig. 26-10). The planar portion of this molecule inserts (intercalates) into the doublehelical DNA between successive G = C base pairs, deforming the DNA. This prevents movement of the polymerase along the template. Because actinomycin D inhibits RNA elongation in intact cells as well as in

cell extracts, it is used to identify cell processes that depend on RNA synthesis. Acridine inhibits RNA synthesis in a similar fashion. Rifampicin inhibits bacterial RNA synthesis by binding to the β subunit of bacterial RNA polymerases, preventing the promoter clearance step of transcription (Fig. 26-6). It is sometimes used as an antibiotic. The mushroom *Amanita phalloides* has a very effective defense mechanism against predators. It produces α -amanitin, which disrupts mRNA formation in animal

Sar Sar Be. L-meVal Bi. TmeVal CH; CH, Acridine (a) cells by blocking Pol II and, at higher concentrations, Pol HI. Neither Pol I nor bacterial RNA polymerase is sensitive to a-amanitin—nor is the RNA polymerase II of *A. phalloides* itself! SUMMARY 26.1 DNA-Dependent Synthesis of RNA > Transcription is catalyzed by DNA-dependent RNA polymerases, which use ribonucleoside 5'-triphosphates to synthesize RNA complementary to the template strand of duplex DNA. Transcription occurs in several phases: binding of RNA polymerase to a DNA site called a promoter, initiation of transcript synthesis, elongation, and termination. > Bacterial RNA polymerase requires a special subunit to recognize the promoter. As the first committed step in transcription, binding of RNA polymerase to the promoter and initiation of transcription are closely regulated. Transcription stops at sequences called terminators. > Eukaryotic cells have three types of RNA polymerases. Binding of RNA polymerase II to its promoters requires an array of proteins called transcription factors. Elongation factors participate in the elongation phase of transcription. The largest subunit of Pol II has a long carboxyl-terminal domain, which is phosphorylated during the initiation and elongation phases. 26.2 RNA Processing Many of the RNA molecules in bacteria and virtually all RNA molecules in eukaryotes are processed to some degree after synthesis. Some of the most interesting 26.2 RNA Processing 1069 FIGURE 26-10 Actinomycin D and acridine, inhibitors of DNA transcription. (a) The shaded portion of actinomycin D is planar and intercalates between two successive G = C base pairs in duplex DNA. The two cyclic peptide moieties of actinomycin D bind to the minor groove of the double helix. Sarcosine (Sar) is N-methylglycine; meVal is methylvaline. Acridine also acts by intercalation in DNA. (b) A complex of actinomycin D with DNA (PDB ID 1DSC). The DNA backbone is shown in blue, the bases are white, the intercalated part of actinomycin (shaded in (a)) is orange, and the remainder of the actinomycin is red. The DNA is bent as a result of the actinomycin binding. (b) molecular events in RNA metabolism occur during this postsynthetic processing. Intriguingly, several of the enzymes that catalyze these reactions consist of RNA rather than protein. The discovery of these catalytic RNAs, or ribozymes, has brought a revolution in thinking about RNA function and about the origin of life. A newly synthesized RNA

molecule is called a primary transcript. Perhaps the most extensive processing of primary transcripts occurs in eukaryotic mRNAs and in tRNAs of both bacteria and eukaryotes. Specialfunction RNAs are also processed. The primary transcript for a eukaryotic mRNA typically contains sequences encompassing one gene, although the sequences encoding the polypeptide may not be contiguous. Noncoding tracts that break up the coding region of the transcript are called introns, and the coding segments are called exons (see the discussion of introns and exons in DNA in Chapter 24). In a process called RNA splicing, the introns are removed from the primary transcript and the exons are joined to form a continuous sequence that specifies a functional polypeptide. Eukaryotic mRNAs are also modified at each end. A modified residue called a 5' cap is added at the 5' end. The 3' end is cleaved, and 80 to 250 A residues are added to create a poly(A) "tail." The sometimes elaborate protein complexes that carry out each of these three mRNA-processing reactions do not operate independently. They seem to be organized in association with each other and with the phosphorylated CTD of Pol II; each complex affects the function of the others. Proteins involved in mRNA transport to the cytoplasm are also associated with the mRNA in the nucleus, and the processing of the transcript is coupled to its transport. In effect, a eukaryotic mRNA, as it is synthesized,

1070 = RNA Metabolism is ensconced in an elaborate complex involving dozens of proteins. The composition of the complex changes as the primary transcript is processed, transported to the cytoplasm, and delivered to the ribosome for translation. The associated proteins modulate all aspects of the function and fate of the mRNA. These processes are outlined in Figure 26-11 and described in more detail below. The primary transcripts of bacterial and eukaryotic tRNAs are processed by the removal of sequences from each end (cleavage) and in a few cases by the removal of introns (splicing). Many bases and sugars in tRNAs are also modified; mature tRNAs are replete with unusual bases not found in other nucleic acids (see Fig. 26-22). Many of the special-function RNAs also undergo elaborate processing, often involving the removal of segments from one or both ends. The ultimate fate of any RNA is its complete and regulated degradation. The rate of turnover of RNAs plays a critical role in determining their steady-state levels and the rate at which cells can shut down expression of a gene whose product is no longer needed. During the development of multicellular organisms, for example, certain proteins must be expressed at one stage only, and the mRNA encoding such a protein must be made and destroyed at the appropriate times. Eukaryotic mRNAs Are Capped at the 5' End Most eukaryotic mRNAs have a 5' cap, a residue of 7-methylguanosine linked to the 5'-terminal residue of transcription and 5' capping DNA Exon Intron 5'Cap completion of primary transcript Primary Noncoding transcript end sequence 5' 3' ! \ ` \ \ N My | f 1 \ ` N \ 1 ! ; \ N cleavage, ? \ : I X polyadenylation, i ~O y x and splicing oe, Y \ \ x Nal Vy Mature ` M 4 y I mRNA -AAA(A)_n 3' FIGURE 26-11 Formation of the primary transcript and its processing during maturation of mRNA in a eukaryotic cell. The 5' cap (red) is added before synthesis of the primary transcript is complete. A noncoding end sequence (intron) following the last exon is shown in orange. Splicing can occur either before or after the cleavage and polyadenylation steps. All the processes shown here take place in the nucleus. the mRNA through an unusual 5' ,5'-triphosphate linkage (Fig. 26-12). The 5' cap helps protect mRNA from ribonucleases. It also binds to a specific cap-binding complex of proteins and participates in binding of the mRNA to the ribosome to initiate translation (Chapter 27). The 5' cap is formed by condensation of a molecule of GTP with the

triphosphate at the 5' end of the transcript. The guanine is subsequently methylated at N-7, and additional methyl groups are often added at the 2' hydroxyls of the first and second nucleotides adjacent to the cap (Fig. 26-12a). The methyl groups are derived from S-adenosylmethionine. All these reactions occur very early in transcription, after the first 20 to 30 nucleotides of the transcript have been added. All three of the capping enzymes, and through them the 5' end of the transcript itself, are associated with the RNA polymerase II CTD until the cap is synthesized. The capped 5' end is then released from the capping enzymes and bound by the cap-binding complex (Fig. 26-12c).

Both Introns and Exons Are Transcribed from DNA into RNA

In bacteria, a polypeptide chain is generally encoded by a DNA sequence that is colinear with the amino acid sequence, continuing along the DNA template without interruption until the information needed to specify the polypeptide is complete. However, the notion that all genes are continuous was disproved in 1977 when Phillip Sharp and Richard Roberts independently discovered that many genes for polypeptides in eukaryotes are interrupted by noncoding sequences (introns). The vast majority of genes in vertebrates contain introns; among the few exceptions are those that encode histones. The occurrence of introns in other eukaryotes varies. Many genes in the yeast *Saccharomyces cerevisiae* lack introns, although in some other yeast species introns are more common. Introns are also found in a few bacterial and archaeal genes. Introns in DNA are transcribed along with the rest of the gene by RNA polymerases. The introns in the primary RNA transcript are then spliced, and the exons are joined to form a mature, functional RNA. In eukaryotic mRNAs, most exons are less than 1,000 nucleotides long, with many in the 100 to 200 nucleotide size range, encoding stretches of 30 to 60 amino acids within a longer polypeptide. Introns vary in size from 50 to 20,000 nucleotides. Genes of higher eukaryotes, including humans, typically have much more DNA devoted to introns than to exons. Many genes have introns; some genes have dozens of them.

RNA Catalyzes the Splicing of Introns

There are four classes of introns. The first two, the group I and group II introns, differ in the details of their splicing mechanisms but share one surprising characteristic: they are self-splicing—no protein enzymes are involved. Group I introns are found in some nuclear,

 Methylguanosine (m'G) is joined to the 5' end of almost all
 eukaryotic mRNAs in an unusual 5',5'-triphosphate linkage. Methyl
 groups (light red) are often found at the 2' position of the first and
 second nucleotides. RNAs in yeast cells lack the 2'-methyl groups.
 The 2'-methyl group on the second nucleotide mitochondrial, and
 chloroplast genes that code for rRNAs, mRNAs, and tRNAs. Group II
 introns are generally found in the primary transcripts of
 mitochondrial or chloroplast mRNAs in fungi, algae, and plants.
 Group I and group II introns are also found among the rare
 examples of introns in bacteria. Neither class requires a high-energy
 cofactor (such as ATP) for splicing. The splicing mechanisms in both
 groups involve two transesterification reaction steps (Fig. 26-13), in
 which a ribose 2'- or 3'-hydroxyl group makes a nucleophilic attack
 on a phosphorus and a new phosphodiester bond is formed at the
 expense of the old, maintaining the balance of energy. These
 reactions are very similar to the DNA breaking and rejoining
 reactions promoted by topoisomerases (see Fig. 24-20) and site-
 specific recombinases (see Fig. 25-37). The group I splicing reaction
 requires a guanine nucleoside or nucleotide cofactor, but the
 cofactor is not £2 GTP CH, fer 5! guanylyltransferase H PP, is
 generally found only in RNAs from vertebrate cells. (b) Generation
 of the 5' cap involves four to five separate steps (adoHcy is S-
 adenosylhomocysteine). (c) Synthesis of the cap is carried out by
 enzymes tethered to the CTD of Pol II. The cap remains tethered to
 the CTD through an association with the cap-binding complex
 (CBC). used as a source of energy; instead, the 3'-hydroxyl group of
 guanosine is used as a nucleophile in the first step of the splicing
 pathway. The guanosine 3'-hydroxyl group forms a normal 3',5'-
 phosphodiester bond with the 5' end of the intron (Fig. 26-14). The
 3' hydroxyl of the exon that is displaced in this step then acts as a
 nucleophile in a similar reaction at the 3' end of the intron. The
 result is precise excision of the intron and ligation of the exons. In

group II introns the reaction pattern is similar except for the nucleophile in the first step, which in this case is the 2'-hydroxyl group of an A residue within the intron (Fig. 26-15). A branched lariat structure is formed as an intermediate. Self-splicing of introns was first revealed in 1982 in studies of the splicing mechanism of the group I rRNA intron from the ciliated protozoan *Tetrahymena thermophila*, conducted by Thomas Cech and colleagues.

1072 RNA Metabolism

FIGURE 26-13 Transesterification reaction. Shown here is the first step in the two-step Exon splicing of group I introns. In this example, the 3' OH of a guanosine molecule acts as nucleophile, attacking the phosphodiester linkage between U and A residues at an exon-intron junction of an mRNA molecule (see Fig. 26-14). Guanosine

These workers transcribed isolated *Tetrahymena* DNA (including the intron) in vitro using purified bacterial RNA polymerase. The resulting RNA spliced itself accurately without any protein enzymes from *Tetrahymena*. The discovery that RNAs could have catalytic functions was a milestone in our understanding of biological systems.

Thomas Cech 3' Most introns are not self-splicing, and these types are not designated with a group number. The third and largest class of introns includes those found in nuclear mRNA primary transcripts. These are called spliceosomal introns, because their removal occurs within and is catalyzed by a large protein complex called a spliceosome. Within the spliceosome, the introns undergo splicing by the same lariat-forming mechanism as the group II introns. The spliceosome is made up of specialized RNA-protein complexes, small nuclear ribonucleoproteins (snRNPs, often pronounced snurps). Each snRNP contains one of a class of eukaryotic RNAs, 100 to 200

Intron Primary transcript 5' Exon 3' Exon 5' U pU 3' The 3' OH of guanosine s. acts as a nucleophile, pG —OH attacking the phosphate at the 5' splice site. Intermediate 5 U —OH pU 3 The 3' OH of the 5'exon becomes the nucleophile, completing the reaction. 5' **FIGURE 26-14 Splicing mechanism of group I introns.** The nucleophile in the first step may be Spliced RNA 3' guanosine, GMP, GDP, or GTP. The spliced intron 5' Up U m 3/ is eventually degraded.

26.2 RNA Processing 1073 Intron FIGURE 26-15 Splicing mechanism of group II introns. The chemistry is similar to that of group I intron splicing, except for the identity of the nucleophile in the transcript first step and formation of a lariatlike intermediate, in which one branch is a 2',5'-phosphodiester bond. The 2' OH of a specific adenosine in the intron acts as a nucleophile, attacking the 5' splice site to form a lariat structure. 2',5'-Phosphodiester bond Intermediate To 3' end 5' pU The 3' OH of the 5' exon acts as a nucleophile, completing the reaction. Spliced RNA is 3' nucleotides long, known as small nuclear RNAs (snRNAs). Five snRNAs (U1, U2, U4, U5, and U6) involved in splicing reactions are generally found in abundance in eukaryotic nuclei. The RNAs and proteins in snRNPs are highly conserved in eukaryotes from yeasts to humans. mRNA Splicing Spliceosomal introns generally have the dinucleotide sequence GU at the 5' end and AG at the 3' end, and these sequences mark the sites where splicing occurs. The U1 snRNA contains a sequence complementary to sequences near the 5' splice site of nuclear mRNA introns (Fig. 26-16a), and the U1 snRNP binds to this region in the primary transcript. Addition of the U2, U4, U5, and U6 snRNPs leads to formation of the spliceosome (Fig. 26-16b). The snRNPs together contribute five RNAs and about 50 proteins to the core spliceosome, a supramolecular assembly nearly as complex as the ribosome (described in Chapter 27). Perhaps 50 additional proteins are associated with the spliceosome at different stages in the splicing process, with some of these proteins having multiple functions: in splicing, mRNA transport to the cytoplasm, translation, and eventual mRNA degradation. ATP is required for assembly of the spliceosome. Adenosine in the lariat structure has three phosphodiester bonds. OH(3') some, but the RNA cleavage-ligation reactions do not seem to require ATP. Some mRNA introns are spliced by a less common type of spliceosome, in which the U1 and U2 snRNPs are replaced by the U11 and U12 snRNPs. Whereas U1- and U2-containing spliceosomes remove introns with (5')GU and AG(3') terminal sequences, as shown in Figure 26-16, the U11- and U12-containing spliceosomes remove a rare class of introns that have (5')AU and AC(8') terminal sequences to mark the intronic splice sites. The spliceosomes used in nuclear RNA splicing may have evolved from more ancient group II introns, with the snRNPs

replacing the catalytic domains of their self-splicing ancestors. Some components of the splicing apparatus are tethered to the CTD of RNA polymerase II, indicating that splicing, like other RNA processing reactions, is tightly coordinated with transcription (Fig. 26-16c). As the first splice junction is synthesized, it is bound by a tethered spliceosome. The second splice junction is then captured by this complex as it passes, facilitating the juxtaposition of the intron ends and the subsequent splicing process. After splicing, the intron remains in the nucleus and is eventually degraded.

Splicing mechanism in mRNA primary transcripts. (a) RNA pairing interactions in the formation of spliceosome complexes. The U1 snRNA has a sequence near its 5' end that is complementary to the splice site at the 5' end of Intron release the intron. Base pairing of U1 to this region of the primary transcript helps define 5' = ——— m the 5' splice site during spliceosome assembly (us is pseudouridine; see Fig. 26-22). (b) U2 is paired to the intron at a position encompassing the A residue (shaded light red) that becomes the nucleophile during the splicing reaction. Base pairing of U2 snRNA causes a bulge that displaces and helps to activate the adenylate, the 2' OH of which will form the lariat structure through a 2',5'-phosphodiester bond. (b) Assembly of spliceosomes. The U1 and U2 snRNPs bind, then the remaining snRNPs (the U4-U6 complex and U5) bind to form an inactive spliceosome. Internal rearrangements convert this species to an active spliceosome in which U1 and U4 have been expelled and U6 is paired with both the 5' splice site and U2. This is followed by the catalytic steps, which parallel those of the splicing of group II introns (see Fig. 26-15). (c) Coordination of splicing and transcription brings the two splice sites together. See the text for details. The spliceosome is much larger than indicated here. 1074

The fourth class of introns, found in certain tRNAs, is distinguished from the group I and II introns in that the splicing reaction requires ATP and an endonuclease. The splicing endonuclease cleaves the phosphodiester bonds at both ends of the intron, and the two exons are joined by a mechanism similar to the DNA ligase reaction (see Fig. 25-16). Although spliceosomal introns seem to be limited to eukaryotes, the other intron classes are not. Genes with group I and II introns have now been found in both bacteria and bacterial viruses. Bacteriophage T4, for example, has several protein-encoding genes with group I introns. Introns may be more common in archaea than in bacteria. Eukaryotic mRNAs Have a Distinctive 3' End Structure At their 3' end, most eukaryotic mRNAs have a string of 80 to 250 A residues, making up the poly(A) tail. This tail serves as a binding site for one or more specific proteins. The poly(A) tail and its associated proteins probably help protect mRNA from enzymatic destruction. Many bacterial mRNAs also acquire poly(A) tails, but these tails stimulate decay of mRNA rather than protecting it from degradation. The poly(A) tail is added in a multistep process. The transcript is extended beyond the site where the poly(A) tail is to be added, then is cleaved at the poly(A) addition site by an endonuclease component of a large enzyme complex, again associated with the CTD of RNA polymerase II (Fig. 26-17). The mRNA site where cleavage occurs is marked by two sequence elements: the highly conserved sequence (5')AAUAAA(3'), 10 to 30 nucleotides on the 5' side (upstream) of the cleavage site, and a less well-defined sequence rich in G and U residues, 20 to 40 nucleotides downstream of the cleavage site. Cleavage generates the free 3'-hydroxyl group that defines the end of the mRNA, to which A residues are immediately added by polyadenylate polymerase, which catalyzes the reaction $\text{RNA} + n\text{ATP} \longrightarrow \text{RNA} - (\text{AMP})_n + \text{PP}_i$; where $n = 80$ to 250 . This enzyme does not require a template but does require the cleaved mRNA as a primer. The overall processing of a typical eukaryotic mRNA is summarized in Figure 26-18. In some cases the polypeptide-coding region of the mRNA is also modified by RNA "editing" (see Section 27.1 for details). This editing includes processes that add or delete bases in the coding regions of primary transcripts or that change the sequence (by, for example, enzymatic deamination of a C residue to create a U

residue). A particularly dramatic example occurs in trypanosomes, which are parasitic protozoa: large regions of an mRNA are synthesized without any uridylyate, and the U residues are inserted later by RNA editing.

Pol || synthesizes RNA beyond the segment of the transcript containing the cleavage signal sequences, including the highly conserved upstream sequence (5')AAUAAA. This cleavage signal sequence is bound by an enzyme complex that includes an endonuclease, a polyadenylate polymerase, and several other multisubunit proteins involved in sequence recognition, stimulation of cleavage, and regulation of the length of the poly(A) tail, all of which are tethered to the CTD.

@ The RNA is cleaved by the endonuclease at a point 10 to 30 nucleotides 3' to (downstream of) the sequence AAUAAA.

@ The polyadenylate polymerase synthesizes a poly(A) tail 80 to 250 nucleotides long, beginning at the cleavage site.

A Gene Can Give Rise to Multiple Products by Differential RNA Processing

One of the paradoxes of modern genomics is that the apparent complexity of organisms does not correlate with the number of protein-encoding genes or even with the amount of genomic DNA. However, the traditional focus on protein-encoding genes ignores the complexity of an organism's transcriptome. As the functions of RNA are better appreciated, new genomic complexities become apparent. Some eukaryotic mRNA transcripts produce only one mature mRNA and one corresponding polypeptide, but others can be processed in more than one way to produce different mRNAs and thus different polypeptides. The primary transcript contains molecular signals for all the alternative processing pathways, and the pathway favored in a given cell is determined by processing factors, RNA-binding proteins that promote one particular path.

The primary tran- translation script has two poly(A) sites; one predominates in the brain, the other in the thyroid. In the brain, splic- ~ ~” ing eliminates the calcitonin exon (exon 4); in the . j : . . . protease thyroid, this exon is retained. The resulting peptides action are processed further to yield the final hormone products: calcitonin-gene-related peptide (CGRP) 4 in the brain and calcitonin in the thyroid. Calcitonin RNA transcript is processed differently to produce two different hormones: the calcium-regulating hormone calcitonin in rat thyroid and calcitonin-gene-related peptide (CGRP) in rat brain (Fig. 26-20). There are many additional patterns of alternative splicing (Fig. 26-21). Many, perhaps most, of the genes in mammalian genomes are subject to alternative splicing, substantially increasing the number of proteins encoded by the genes. The same processes play a much smaller role in lower eukaryotes, with only a few genes subject to alternative splicing in yeast. Ribosomal RNAs and tRNAs Also Undergo Processing Posttranscriptional processing is not limited to mRNA. Ribosomal RNAs of bacterial, archaeal, and eukaryotic cells are made from longer precursors called preribosomal RNAs, or pre-rRNAs. Transfer RNAs are similarly derived from longer precursors. These RNAs may also contain a variety of modified nucleosides; some examples are shown in Figure 26-22. FIGURE 26-21 Summary of splicing patterns. Exons are shown in shades of green, and introns/untranslated regions as yellow lines. Positions where polyadenosine is to be added are marked with asterisks. Exons joined in a particular splicing scheme are linked with black lines. The alternative linkage patterns above and below the transcript lead to the top and bottom spliced mRNA products, respectively. Note the unusual ribose attachment point in pseudouridine. This is just a small sampling of the 96 modified nucleosides known to occur about 6,500 nucleotides. RNA at both ends of the 30S precursor and segments between the rRNAs are removed during processing (Fig. 26-23). The 16S and 23S rRNAs contain modified nucleosides. In *Æ. coli*, the 11 modifications in the 16S rRNA include a pseudouridine and 10 nucleosides methylated on the base or the 2'-hydroxyl group or both. The 23S rRNA has 10 pseudouridines, 1 dihydrouridine, and 12 methylated nucleosides. In bacteria, each modification is generally catalyzed by a distinct enzyme. Methylation reactions use S-adenosylmethionine as cofactor. No cofactor is required for pseudouridine formation. In different RNA species, with 81 different types known in tRNAs and 30 observed to date in rRNAs. A complete listing of these modified bases can be found in the RNA modification database (<http://rna-mdb.cas.albany.edu/RNAmods/>). The genome of *Æ. coli* encodes seven pre-rRNA molecules. All of these genes have essentially identical rRNA-coding regions, but they differ in the segments between these regions. The segment between the 16S and 23S rRNA genes generally encodes one or two tRNAs, with different tRNAs produced from different pre-rRNA transcripts. Coding sequences for tRNAs are also found on the 3' side of the 5S rRNA in some precursor transcripts. The situation in eukaryotes is more complicated. A 45S pre-rRNA transcript is synthesized by RNA polymerase I and processed in the nucleolus to form the

FIGURE 26-24 Processing of pre-rRNA transcripts in vertebrates. During transcription, the 45S primary transcript is incorporated into a nucleolar 90S preribosomal complex, in which rRNA processing and ribosome assembly are tightly coupled. @ The 45S precursor is methylated at more than 100 of its 14,000 nucleotides, either on the bases or on the 2'-OH groups (red ticks), some uridines are converted to pseudouridine (blue icks), and a few other modifications occur (green ticks are dihydrouridine). @ and @ A series of enzymatic cleavages of the 45S precursor produces the 18S, 5.8S, and 28S rRNAs, and the ribosomal subunits gradually take shape with the assembling ribosomal proteins. The cleavage reactions and all of the modifications require small nucleolar RNAs (snoRNAs) found in protein complexes (snoRNPs) in the nucleolus that are reminiscent of spliceosomes. The 5S rRNA is produced separately.

26.2 RNA Processing 1079

ribosome assembly in the nucleolus. Each complex includes the ribonucleases that cleave the rRNA precursor, the enzymes that modify particular bases, large numbers of small nucleolar RNAs, or snoRNAs, that guide nucleoside modification and some cleavage reactions, and ribosomal proteins. In yeast, the entire process involves the pre-rRNA, more than 170 nonribosomal proteins, snoRNAs for each nucleoside modification (about 70 in all, since some snoRNAs guide two types of modification), and the 78 ribosomal proteins. Humans have an even greater number of modified nucleosides, about 200, and a greater number of associated snoRNAs. The composition of the complexes may change as the ribosomes are assembled, and many of the intermediate

complexes may rival the ribosome itself, and the snRNPs, in complexity. The 5S rRNA of most eukaryotes is made as a completely separate transcript by a different polymerase (Pol III). The most common nucleoside modifications in eukaryotic rRNAs are, again, conversion of uridine to pseudouridine and adMet-dependent nucleoside methylation (often at 2'-hydroxyl groups). These reactions rely on snoRNA-protein complexes, or snoRNPs, each consisting of a snoRNA and four or five proteins, which include the enzyme that carries out the modification. There are two classes of snoRNPs, both defined by key conserved sequence elements referred to as lettered boxes. The box H/ACA snoRNPs are involved in pseudouridylation, and box C/D snoRNPs function in 2'-O-methylations. Unlike the situation in bacteria, the same enzyme may participate in modifications at many sites, guided by the snoRNAs. The snoRNAs are 60 to 300 nucleotides long. Many are encoded within the introns of other genes and cotranscribed with those genes. Each snoRNA includes a 10 to 21 nucleotide sequence that is perfectly complementary to some site on an rRNA. The conserved sequence elements in the remainder of the snoRNA fold into structures that are bound by the snoRNP proteins (Fig. 26-25). Transfer RNAs Most cells have 40 to 50 distinct tRNAs, and eukaryotic cells have multiple copies of many of the tRNA genes. Transfer RNAs are derived from longer RNA precursors by enzymatic removal of nucleotides from the 5' and 3' ends (Fig. 26-26). In eukaryotes, introns are present in a few tRNA transcripts and must be excised. Where two or more different tRNAs are contained in a single primary transcript, they are separated by enzymatic cleavage. The endonuclease RNase P, found in all organisms, removes RNA at the 5' end of tRNAs. This enzyme contains both protein and RNA. The RNA component is essential for activity, and in bacterial cells it can carry out its processing function with precision even without the protein component. RNase P is therefore another example of a catalytic RNA, as described in more detail below. The 3' end of tRNAs is processed by one or more nucleases, including the exonuclease RNase D.

CCA is then added to the 3' end, a necessary step in processing eukaryotic tRNAs and those bacterial tRNAs Box ACA

FIGURE 26-25 The function of snoRNAs in guiding rRNA modification. (a) RNA pairing with box C/D snoRNAs to guide methylation reactions. The methylation sites in the target rRNA (dark green) are in the regions paired with the C/D snoRNA. The highly conserved C and D (and C' and D') box sequences are binding sites or proteins that make up the larger snoRNP. (b) RNA pairing with box H/ACA snoRNAs to guide pseudouridylation. The pseudouridine conversion sites in the target rRNA (green segments) are again in the regions paired with the snoRNA, and the conserved H/ACA box sequences are protein-binding sites. e005! NNN— OH (3') CCA(8') sequence. The creation of this defined sequence of nucleotides is therefore not dependent on a DNA or RNA template—the template is the binding site of the enzyme. The final type of tRNA processing is the modification of some bases by methylation, deamination, or reduction (Fig. 26-22). In the case of pseudouridine, the base (uracil) is removed and reattached to the sugar through C-5. Some of these modified bases occur at characteristic positions in all tRNAs (Fig. 26-26). Intermediate Mature tRNATM y 3: OH OH that lack this sequence in the primary transcript. While the ends are being processed, specific bases in the

rest of the transcript are modified (see Fig. 26-22). For the eukaryotic tRNA shown here, the final step is splicing of the 14 nucleotide intron. Introns are found in some eukaryotic tRNAs but not in bacterial tRNAs.

Special-Function RNAs Undergo Several Types of Processing The number of known classes of special-function RNAs is expanding rapidly, as is the variety of functions known to be associated with them. Many of these RNAs undergo processing. The snRNAs and snoRNAs not only facilitate RNA processing reactions but are themselves synthesized as larger precursors and then processed. Many snoRNAs are encoded within the introns of other genes. As the introns are spliced from the pre-mRNA, the snoRNP proteins bind to the snoRNA sequences and ribonucleases remove the extra RNA at the 5' and 3' ends. The snRNAs destined for spliceosomes are synthesized as pre-snRNAs by RNA polymerase II, and ribonucleases remove the extra RNA at each end. Particular nucleosides in snRNAs are also subject to 11 types of modification, with 2'-O-methylation and conversion of uridine to pseudouridine predominating. MicroRNAs (miRNAs) are a special class of RNAs involved in gene regulation. They are noncoding RNAs, about 22 nucleotides long, complementary in sequence to particular regions of mRNAs. They regulate mRNA function by cleaving the mRNA or suppressing its translation. The miRNAs are found in multicellular eukaryotes ranging from worms and fruit flies to plants and mammals. Up to 1% of the human genome may encode miRNAs, and miRNAs may target up to one-third of human mRNAs. Their function in gene regulation is described in Chapter 28. The miRNAs are synthesized from much larger precursors, in several steps (Fig. 26-27). The primary transcripts for miRNAs (pri-miRNAs) vary greatly in size; some are encoded in the introns of other genes and are coexpressed with these host genes. Their roles in gene regulation also are detailed in Chapter 28. **FIGURE 26-27 Synthesis and processing of miRNAs.** The primary transcript of miRNAs is larger RNA of variable length, a pri-miRNA. Much of its processing is mediated by two endoribonucleases in the RNase III family, Drosha and Dicer. First, in the nucleus, the pri-miRNA is reduced to a 70 to 80 nucleotide precursor miRNA (pre-miRNA) by a protein complex including Drosha and another protein, DGCR8. The pre-miRNA is then exported to the cytoplasm in a complex with a protein called exportin-5 and the Ran GTPase (see Fig. 27-42). In the cytoplasm, Ran hydrolyzes the GTP, then exportin-5 protein and the pre-miRNA are released. The Ran-GDP and exportin-5 proteins are transported back into the nucleus. The pre-miRNA is acted on

by Dicer to produce the nearly mature miRNA paired with a short RNA complement. The complement is removed by an RNA helicase, and the mature miRNA is incorporated into protein complexes, such as the RNA-induced silencing complex (RISC), which then bind a target mRNA. If the complementarity between miRNA and its target is nearly perfect, the target mRNA is cleaved. If the complementarity is only partial, the complex blocks translation of the target mRNA.

1082 RNA Metabolism RNA Enzymes Are the Catalysts of Some Events in RNA Metabolism The study of posttranscriptional processing of RNA molecules led to one of the most exciting discoveries in modern biochemistry—the existence of RNA enzymes. The best-characterized ribozymes are the self-splicing group I introns, RNase P, and the hammerhead ribozyme (discussed below). Most of the activities of these ribozymes are based on two fundamental reactions: transesterification (Fig. 26-13) and phosphodiester bond hydrolysis (cleavage). The substrate for ribozymes is often an RNA molecule, and it may even be part of the ribozyme itself. When its substrate is RNA, the RNA catalyst can make use of base-pairing interactions to align the substrate for the reaction. Ribozymes vary greatly in size. A self-splicing group I intron may have more than 400 nucleotides. The hammerhead ribozyme consists of two RNA strands with only 41 nucleotides in all (Fig. 26-28). As with protein enzymes, the three-dimensional structure of ribozymes is important for function. Ribozymes are inactivated by heating above their melting temperature or by addition of denaturing agents or complementary oligonucleotides, which disrupt normal base-pairing patterns. Ribozymes can also be inactivated if essential nucleotides are changed. The secondary structure of a selfsplicing group I intron from the 26S rRNA precursor of *Tetrahymena* is shown in detail in Figure 26-29.

Enzymatic Properties of Group I Introns Self-splicing group I introns share several properties with enzymes besides accelerating the reaction rate, including their kinetic behavior and their specificity. Binding of the guanosine cofactor (Fig. 26-13) to the *Tetrahymena* group I rRNA intron is saturable ($K_m \sim 30 \mu\text{M}$) and can be competitively inhibited by 3'-deoxyguanosine. The intron is very precise in its excision reaction, largely due to a segment called the internal guide sequence that can base-pair with exon sequences near the 5' splice site (Fig. 26-29). This pairing promotes the alignment of specific bonds to be cleaved and rejoined. Because the intron itself is chemically altered during the splicing reaction—its ends are cleaved—it may seem to lack one key enzymatic property: the ability to catalyze multiple reactions. Closer inspection has shown that after excision, the 414 nucleotide intron from *Tetrahymena* rRNA can, in vitro, act as a true enzyme (but in vivo it is quickly degraded). A series of intramolecular cyclization and

cleavage reactions in the excised intron leads to the loss of 19 nucleotides from its 5' end. The remaining 395 nucleotide, linear RNA—referred to as L-19 IVS (intervening sequence)—promotes nucleotidyl transfer reactions in which some oligonucleotides are lengthened at the expense of others (Fig. 26-30). The best substrates are oligonucleotides, such as a synthetic (C); oligomer, that can base-pair with the same FIGURE 26-28 Hammerhead ribozyme. Certain viruslike elements, or virusoids, have small RNA genomes and usually require another virus to assist in their replication or packaging or both. Some virusoid RNAs include small segments that promote site-specific RNA cleavage reactions associated with replication. These segments are called hammerhead ribozymes, because their secondary structures are shaped like the head of a hammer. Hammerhead ribozymes have been defined and studied separately from the much larger viral RNAs. (a) The minimal sequences required for catalysis by the ribozyme. The boxed nucleotides are highly conserved and are required for catalytic function. The arrow indicates the site of self-cleavage. (b) Three-dimensional structure (PDB ID IMME; see Fig. 8-25b for a space-filling view). The strands are colored as in (a). The hammerhead ribozyme is a metalloenzyme; Mg^{2+} ions are required for activity in vivo. The phosphodiester bond at the site of self-cleavage is indicated by an arrow. é Hammerhead Ribozyme guanylate-rich internal guide sequence that held the 5' exon in place for self-splicing. The enzymatic activity of the L-19 IVS ribozyme results from a cycle of transesterification reactions mechanistically similar to self-splicing. Each ribozyme molecule can process about 100 substrate molecules per hour and is not altered in the reaction; therefore the intron acts as a catalyst. It follows Michaelis-Menten kinetics, is specific for RNA oligonucleotide substrates, and can be competitively inhibited. The k_{cat}/K_m (specificity constant) is $10^6 \text{ m}^{-1} \text{ s}^{-1}$, lower than that of many enzymes, but the ribozyme accelerates hydrolysis by a factor of 10^6 relative

(b) FIGURE 26-29 Secondary structure of the self-splicing rRNA intron of *Tetrahymena*. (a) Intron sequences are shaded yellow and light red, exon sequences green. Each thin, light red line represents a bond between neighboring nucleotides in a continuous sequence (a device necessitated by showing this complex molecule in two dimensions). Short blue lines represent normal base pairing; blue dots indicate G-U base pairs. All nucleotides are shown. The catalytic core of the self-splicing activity is shaded in gray. Some base-paired regions are labeled (P1, P3, P2.1, P5a, and to the uncatalyzed reaction. It makes use of substrate orientation, covalent catalysis, and metal-ion catalysis— strategies used by protein enzymes. Characteristics of Other Ribozymes *E. coli* RNase P has both an RNA component (the M1 RNA, with 377 nucleotides) and a protein component (M, 17,500). In 1983 Sidney Altman and Norman Pace and their coworkers discovered that under some conditions, the M1 RNA alone is capable of catalysis, cleaving tRNA precursors at the correct position. The protein component apparently serves to stabilize the RNA or facilitate its function in vivo. The RNase P ribozyme recognizes the three-dimensional shape of its pre-tRNA substrate, along with the CCA sequence, and thus can cleave the 5' leaders from diverse tRNAs (Fig. 26-26). Internal guide sequence 26.2 RNA Processing 1083 so forth) according to an established convention for this RNA molecule. The P1 region, which contains the internal guide sequence (purple), is the location of the 5' splice site (black arrow). Part of the internal guide sequence pairs with the end of the 3' exon, bringing the 5' and 3' splice sites (black arrows) into close proximity. (b) (PDB ID 1GID) The three-dimensional structure of the P4-P6 domain, shown in yellow in (a). (c) (PDB 2 ID 1U6B) The three-dimensional structure of most of the remainder of the intron, shown in light red in (a). The known catalytic repertoire of ribozymes continues to expand. Some virusoids, small RNAs associated with plant RNA viruses, include a structure that promotes a self-cleavage reaction; the hammerhead ribozyme illustrated in Figure 26-28 is in this class, catalyzing the hydrolysis of an internal phosphodiester bond. The splicing reaction that occurs in a spliceosome seems to rely on a catalytic center formed by the U2, U5, and U6 snRNAs (Fig. 26-16). And perhaps most important, an RNA component of ribosomes catalyzes the synthesis of proteins (Chapter 27). Exploring catalytic RNAs has

provided new insights into catalytic function in general and has important implications for our understanding of the origin and evolution of life on this planet, a topic discussed in Section 26.3.

IVS lengthens some RNA oligonucleotides at the expense of others
in a cycle of transesterification reactions Cellular mRNAs Are
Degraded at Different Rates The expression of genes is regulated at
many levels. A crucial factor governing a gene's expression is the
cellular concentration of its associated mRNA. The concentration of
any molecule depends on two factors: its rate of synthesis and its
rate of degradation. When synthesis and degradation of an mRNA
are balanced, the concentration of the mRNA remains in a steady
state. A change in either rate will lead to net accumulation or
depletion of the mRNA. Degradative pathways ensure that mRNAs
do not build up in the cell and direct the synthesis of unnecessary
proteins. The rates of degradation vary greatly for mRNAs from
different eukaryotic genes. For a gene product that is needed only
briefly, the half-life of its mRNA may be only minutes or even
seconds. Gene products needed constantly by the cell may have
mRNAs that are stable over many cell generations. The average
half-life of the mRNAs of a vertebrate cell is about 3 hours, with the
pool of each type of mRNA turning over about 10 times per (steps
@ through @). The 3' OH of the G residue at the 3' end of L-19 IVS
plays a key role in this cycle (note that this is not the G residue
added in the splicing reaction). (C); is one of the ribozyme's better
substrates because it can base-pair with the guide sequence
remaining in the intron. Although this catalytic activity is probably
irrelevant to the cell, it has important implications for current
hypotheses on evolution, discussed at the end of this chapter. cell

generation. The half-life of bacterial mRNAs is much shorter—only about 1.5 min—perhaps because of regulatory requirements. Messenger RNA is degraded by ribonucleases present in all cells. In *E. coli*, the process begins with one or several cuts by an endoribonuclease, followed by 3'→5' degradation by exoribonucleases. In lower eukaryotes, the major pathway involves first shortening the poly(A) tail, then decapping the 5' end and degrading the mRNA in the 5'→3' direction. A 3'→5' degradative pathway also exists and may be the major path in higher eukaryotes. All eukaryotes have a complex of up to 10 conserved 3'→5' exoribonucleases, called the exosome, which is involved in the processing of the 3' end of rRNAs, tRNAs, and some special-function RNAs (including snRNAs and snoRNAs), as well as the degradation of mRNAs. A hairpin structure in bacterial mRNAs with a p-independent terminator (Fig. 26-7) confers stability against degradation. Similar hairpin structures can make some parts of a primary transcript more stable, leading to

nonuniform degradation of transcripts. In eukaryotic cells, both the 3' poly(A) tail and the 5' cap are important to the stability of many mRNAs.

6 Life Cycle of an mRNA

Polynucleotide Phosphorylase Makes Random RNA-like Polymers

In 1955, Marianne Grunberg-Manago and Severo Ochoa discovered the bacterial enzyme polynucleotide phosphorylase, which in vitro catalyzes the reaction $(\text{NMP})_n + \text{NDP} \rightleftharpoons (\text{NMP})_{n+1} + \text{P}$. Lengthened polynucleotide Polynucleotide phosphorylase was the first nucleic acid—synthesizing enzyme discovered (Arthur Kornberg's discovery of DNA polymerase followed soon thereafter). The reaction catalyzed by polynucleotide phosphorylase differs fundamentally from the polymerase activities discussed so far in that it is not template-dependent. The enzyme uses the 5'-diphosphates of ribonucleosides as substrates and cannot act on the homologous 5'-triphosphates or on deoxyribonucleoside 5'-diphosphates. The RNA polymer formed by polynucleotide phosphorylase contains the usual 3',5'-phosphodiester linkages, which can be hydrolyzed by ribonuclease. The reaction is readily reversible and can be pushed in the direction of breakdown of the polyribonucleotide by increasing the phosphate concentration. The probable function of this enzyme in the cell is the degradation of mRNAs to nucleoside diphosphates.

Severo Ochoa, 1905-1993
Marianne Grunberg-Manago

Because the polynucleotide phosphorylase reaction does not use a template, the polymer it forms does not have a specific base sequence. The reaction proceeds equally well with any or all of the four nucleoside diphosphates, and the base composition of the resulting polymer reflects nothing more than the relative concentrations of the 5'-diphosphate substrates in the medium. Polynucleotide phosphorylase can be used in the laboratory to prepare RNA polymers with many different base sequences and frequencies. Synthetic RNA polymers of this sort were critical for deducing the genetic code for the amino acids (Chapter 27).

26.3 RNA-Dependent Synthesis of RNA and DNA

1085 SUMMARY

26.2 RNA Processing

> Eukaryotic mRNAs are modified by addition of a 7-methylguanosine residue at the 5' end and by cleavage and polyadenylation at the 3' end to form a long poly(A) tail. > Many primary mRNA transcripts contain introns (noncoding regions), which are removed by splicing. Excision of the group I introns found in some rRNAs requires a guanosine cofactor.

Some group I and group II introns are capable of selfsplicing; no protein enzymes are required. Nuclear mRNA precursors have a third (the largest) class of introns, which are spliced with the aid of RNAprotein complexes called snRNPs, assembled into spliceosomes. A fourth class of introns, found in some tRNAs, consists of the only introns known to be spliced by protein enzymes. > The function of many eukaryotic mRNAs is regulated by complementary microRNAs (miRNAs). The miRNAs are themselves derived from larger precursors through a series of processing reactions. > Ribosomal RNAs and transfer RNAs are derived from longer precursor RNAs, trimmed by nucleases. Some bases are modified enzymatically during the maturation process. Some nucleoside modifications are guided by snoRNAs, within protein complexes called snoRNPs. > The self-splicing introns and the RNA component of RNase P (which cleaves the 5' end of tRNA precursors) are two examples of ribozymes. These biological catalysts have the properties of true enzymes. They generally promote hydrolytic cleavage and transesterification, using RNA as substrate. Combinations of these reactions can be promoted by the excised group I intron of Tetrahymena rRNA, resulting in a type of RNA polymerization reaction. > Polynucleotide phosphorylase reversibly forms RNA-like polymers from ribonucleoside 5'-diphosphates, adding or removing ribonucleotides at the 3'-hydroxyl end of the polymer. The enzyme degrades RNA in vivo.

26.3 RNA-Dependent Synthesis of RNA and DNA

In our discussion of DNA and RNA synthesis up to this point, the role of the template strand has been reserved for DNA. However, some enzymes use an RNA template for nucleic acid synthesis. With the very important exception of viruses with an RNA genome, these enzymes play only a modest role in information pathways. RNA viruses are the source of most RNA-dependent polymerases characterized so far.

1086 RNA Metabolism DNA replication Transcription Translation Protein

FIGURE 26-31 Extension of the central dogma to include RNA-dependent synthesis of RNA and DNA. Reverse transcriptase The existence of RNA replication requires an elaboration of the central dogma (Fig. 26-31; contrast this with the diagram on p. 977). The enzymes involved in RNA replication have profound implications for investigations into the nature of self-replicating molecules that may have existed in prebiotic times.

Reverse Transcriptase Produces DNA from Viral RNA Certain RNA viruses that infect animal cells carry within the viral particle an RNA-dependent DNA polymerase called reverse transcriptase. On infection, the singlestranded RNA viral genome (~10,000 nucleotides) and the enzyme enter the host cell. The reverse transcriptase first catalyzes the synthesis of a DNA strand complementary to the viral RNA (Fig. 26-32), then degrades the RNA strand of the viral RNA-DNA hybrid and replaces it with DNA. The resulting duplex DNA often becomes incorporated into the genome of the host cell.

Assembly and packaging Translation and proteolysis Plasma membrane Reverse transcription

FIGURE 26-32 Retroviral infection of a mammalian cell and integration of the retrovirus into the host chromosome. Viral particles entering the host cell carry viral reverse transcriptase and from a former host cell) already base-paired segments represent the long terminal repeats a cellular tRNA (picked up by the viral RNA. The tRNA facilitates immediate conversion of viral RNA to double-stranded DNA by the action of reverse transcriptase, as double-stranded DNA, the DNA enters the nucleus and is integrated into the host genome. The integration is catalyzed by a virally encoded integrase. Integration of viral DNA into host DNA is mechanistically similar to the insertion of transposons in bacterial chromosomes (see Fig. 25-41). For example, a few base pairs of host DNA become duplicated at the site of integration, forming short repeats of 4 to 6 bp at each end of the inserted retroviral DNA (not shown). On transcription and translation of the integrated viral DNA, new viruses are formed and released by cell lysis (right). In the viruses, the viral RNA is enclosed by capsid proteins called Gag and outer

envelope proteins called Env. Additional viral proteins (reverse transcriptase, integrase, and a viral protease needed for posttranslational processing of viral proteins) are packaged within the virus particle with the RNA.

viral genes can be activated and transcribed, and the gene products—viral proteins and the viral RNA genome itself—packaged as new viruses. The RNA viruses that contain reverse transcriptases are known as retroviruses (retro is the Latin prefix for “backward”). The existence of reverse transcriptases in RNA viruses was predicted by Howard Temin in 1962, and the enzymes were ultimately detected by Temin and, independently, by David Baltimore in 1970. Their discovery aroused much attention as dogma-shaking proof that genetic information can flow “backward” from RNA to DNA. Howard Temin, 1934-1994 David Baltimore

Retroviruses typically have three genes: gag (a name derived from the historical designation group associated antigen), pol, and env (Fig. 26-33). The transcript that contains gag and pol is translated into a long “polyprotein,” a single large polypeptide that is cleaved into six proteins with distinct functions. The proteins derived from the gag gene make up the interior core of the viral particle. The pol gene encodes the protease that cleaves the long polypeptide, an integrase that inserts the viral DNA into the host chromosomes, and reverse transcriptase. Many reverse transcriptases have two subunits, a and B. The pol gene specifies the B subunit (W, 90,000), and the a subunit (M, 65,000) is simply a proteolytic fragment of the 6 subunit. The env gene encodes the proteins of the viral envelope. At each end of the linear RNA genome are long terminal repeat (LTR) sequences of a few hundred nucleotides. Transcribed into the duplex DNA, these sequences facilitate integration of the viral chromosome into the host DNA and contain promoters for viral gene expression. Reverse transcriptases catalyze three different reactions: (1) RNA-dependent DNA synthesis, (2) RNA degradation, and (3) DNA-dependent DNA synthesis. Like many DNA and RNA polymerases, reverse transcriptases contain Zn²⁺. Each transcriptase is most active with the RNA of its own virus, but each can be used experimentally to make DNA complementary to a variety of RNAs. The DNA and RNA synthesis and RNA degradation activities use separate active sites on the protein. For DNA synthesis to begin, the reverse transcriptase requires a primer, a cellular tRNA obtained during an earlier infection and carried in the viral particle. This

FIGURE 26-33 Structure and gene products of an integrated retroviral genome. The long terminal repeats (LTRs) have sequences needed for the regulation and initiation of transcription. The sequence denoted ψ is required for packaging of retroviral RNAs into mature viral particles. Transcription of the retroviral DNA produces a primary transcript encompassing the gag, pol, and env genes. Translation (Chapter 27) produces a polyprotein, a single long polypeptide derived from the gag and pol genes, which is cleaved into six distinct proteins. Splicing of the primary transcript yields an mRNA derived largely from the env gene, which is also translated into a polyprotein, then cleaved to generate viral envelope proteins. tRNA is base-paired at its 3' end with a complementary sequence in the viral RNA. The new DNA strand is synthesized in the 5'—> 3' direction, as in all RNA and DNA polymerase reactions. Reverse transcriptases, like RNA polymerases, do not have 3'—5' proofreading exonucleases. They generally have error rates of about 1 per 20,000 nucleotides added. An error rate this high is extremely unusual in DNA replication and seems to be a feature of most enzymes that replicate the genomes of RNA viruses. A consequence is a higher mutation rate and faster rate of viral evolution, which is a factor in the frequent appearance of new strains of disease-causing retroviruses. Reverse transcriptases have become important reagents in the study of DNA-RNA relationships and in DNA cloning techniques. They make possible the synthesis of DNA complementary to an mRNA template, and synthetic DNA prepared in this manner, called complementary DNA (cDNA), can be used to clone cellular genes (see Fig. 9-14).

The src gene encodes a tyrosine kinase, one of a class of enzymes that function in systems affecting cell division, cell-cell interactions, and intercellular communication (Chapter 12). The same gene is found in chicken DNA (the usual host for this virus) and in the genomes of many other eukaryotes, including humans. When associated with the Rous sarcoma virus, this oncogene is often expressed at abnormally high levels, contributing to unregulated cell division and cancer. vpr— > rev rev gag vif tat tat -- nef vpu pol LTR env LTR FIGURE 26-35 The genome of HIV, the virus that causes AIDS. In addition to the typical retroviral genes, HIV contains several small genes with a variety of functions (not identified here and not all known). Some

Some Retroviruses Cause Cancer and AIDS Retroviruses have featured prominently in recent advances in the molecular understanding of cancer. Most retroviruses do not kill their host cells but remain integrated in the cellular DNA, replicating when the cell divides. Some retroviruses, classified as RNA tumor viruses, contain an oncogene that can cause the cell to grow abnormally. The first retrovirus of this type to be studied was the Rous sarcoma virus (also called avian sarcoma virus; Fig. 26-34), named for F. Peyton Rous, who studied chicken tumors now known to be caused by this virus. Since the initial discovery of oncogenes by Harold Varmus and Michael Bishop, many dozens of such genes have been found in retroviruses. The human immunodeficiency virus (HIV), which causes acquired immune deficiency syndrome (AIDS), is a retrovirus. Identified in 1983, HIV has an RNA genome with standard retroviral genes along with several other unusual genes (Fig. 26-35). Unlike many other retroviruses, HIV kills many of the cells it infects (principally T lymphocytes) rather than causing tumor formation. This gradually leads to suppression of the immune system in the host organism. The reverse transcriptase of HIV is even more error-prone than other known reverse transcriptases—10 times more so— resulting in high mutation rates in this virus. One or more errors are generally made every time the viral genome is replicated, so any two viral RNA molecules are likely to differ. Many modern vaccines for viral infections consist of one or more coat proteins of the virus, produced by methods described in Chapter 9. These proteins are not infectious on their own but

stimulate the immune system to recognize and resist subsequent viral invasions (Chapter 5). Because of the high error rate of the HIV reverse transcriptase, the *env* gene in this virus (along of these genes overlap. Alternative splicing mechanisms produce many different proteins from this small (9.7×10^6 nucleotides) genome. with the rest of the genome) undergoes very rapid mutation, complicating the development of an effective vaccine. However, repeated cycles of cell invasion and replication are needed to propagate an HIV infection, so inhibition of viral enzymes offers the most effective therapy currently available. The HIV protease is targeted by a class of drugs called protease inhibitors (see Fig. 6-24). Reverse transcriptase is the target of some additional drugs widely used to treat HIV-infected individuals (Box 26-2).

E Many Transposons, Retroviruses, and Introns May Have a Common Evolutionary Origin

Some well-characterized eukaryotic DNA transposons from sources as diverse as yeast and fruit flies have a structure very similar to that of retroviruses; these are sometimes called retrotransposons (Fig. 26-36). Retrotransposons encode an enzyme homologous to the retroviral reverse transcriptase, and their coding regions are flanked by LTR sequences. They transpose from one position to another in the cellular genome by means of an RNA intermediate, using reverse transcriptase to

Eukaryotic transposons. The Ty element of the yeast *Saccharomyces* and the copia element of the fruit fly *Drosophila* serve as examples of eukaryotic retrotransposons, which often have a structure similar to retroviruses but lack the *env* gene. The 6 sequences of the Ty element are functionally equivalent to retroviral LTRs. In the copia element, INT and RT are homologous to the integrase and reverse transcriptase segments, respectively, of the pol gene.

26.3 RNA-Dependent Synthesis of RNA and DNA 1089 BOX

26-2 E MEDICINE Fighting AIDS with Inhibitors of HIV Reverse Transcriptase Research into the chemistry of template-dependent nucleic acid biosynthesis, combined with modern techniques of molecular biology, has elucidated the life cycle and structure of the human immunodeficiency virus, the retrovirus that causes AIDS. A few years after the isolation of HIV, this research resulted in the development of drugs capable of prolonging the lives of people infected by HIV. The first drug to be approved for clinical use was AZT, a structural analog of deoxythymidine. AZT was first synthesized in 1964 by Jerome P. Horwitz. It failed as an anticancer drug (the purpose for which it was made), but in 1985 it was found to be a useful treatment for AIDS. AZT is taken up by T lymphocytes, immune system cells that are particularly vulnerable to 3'-Azido-2',3'-dideoxythymidine (AZT) 2',3'-Dideoxyinosine (DDI) make a DNA copy of the RNA, followed by integration of the DNA at a new site. Most transposons in eukaryotes use this mechanism for transposition, distinguishing them from bacterial transposons, which move as DNA directly from one chromosomal location to another (see Fig. 25-41). Retrotransposons lack an env gene and so cannot form viral particles. They can be thought of as defective viruses, trapped in cells. Comparisons between retroviruses and eukaryotic transposons suggest that reverse transcriptase is an ancient enzyme that predates the evolution of multicellular organisms. Interestingly, many group I and group II introns are also mobile genetic elements. In addition to their self-splicing activities, they encode DNA endonucleases that promote their movement. During genetic exchanges between cells of the same species, or when DNA is introduced into a cell by parasites or by other means, these endonucleases promote insertion of the intron into an identical site in another DNA copy of a homologous gene that does not contain the intron, in a process termed homing (Fig. 26-37). Whereas group I intron homing is DNA-based, group II intron homing occurs HIV infection, and converted to AZT triphosphate. (AZT triphosphate taken directly would be ineffective because it cannot cross the plasma membrane.) HIV's reverse transcriptase has a higher affinity for AZT triphosphate than for dTTP, and binding of AZT triphosphate to this enzyme competitively inhibits dTTP binding. When AZT is added to the 3' end of the growing DNA

strand, lack of a 3' hydroxyl means that the DNA strand is terminated prematurely and viral DNA synthesis grinds to a halt. AZT triphosphate is not as toxic to the T lymphocytes themselves because cellular DNA polymerases have a lower affinity for this compound than for dTTP. At concentrations of 1 to 5 μ M, AZT affects HIV reverse transcription but not most cellular DNA replication. Unfortunately, AZT seems to be toxic to the bone marrow cells that are the progenitors of erythrocytes, and many individuals taking AZT develop anemia. AZT can increase the survival time of people with advanced AIDS by about a year, and it delays the onset of AIDS in those who are still in the early stages of HIV infection. Some other AIDS drugs, such as dideoxyinosine (DDI), have a similar mechanism of action. Newer drugs target and inactivate the HIV protease. Because of the high error rate of HIV reverse transcriptase and the resulting rapid evolution of HIV, the most effective treatments of HIV infection use a combination of drugs directed at both the protease and the reverse transcriptase. through an RNA intermediate. The endonucleases of the group II introns have associated reverse transcriptase activity. The proteins can form complexes with the intron RNAs themselves, after the introns are spliced from the primary transcripts. Because the homing process involves insertion of the RNA intron into DNA and reverse transcription of the intron, the movement of these introns has been called retrohoming. Over time, every copy of a particular gene in a population may acquire the intron. Much more rarely, the intron may insert itself into a new location in an unrelated gene. If this event does not kill the host cell, it can lead to the evolution and distribution of an intron in a new location. The structures and mechanisms used by mobile introns support the idea that at least some introns originated as molecular parasites whose evolutionary past can be traced to retroviruses and transposons. Telomerase Is a Specialized Reverse Transcriptase Telomeres, the structures at the ends of linear eukaryotic chromosomes (see Fig. 24-8), generally consist of many tandem copies of a short oligonucleotide sequence.

BOX 26-2 MEDICINE Fighting AIDS with Inhibitors of HIV Reverse Transcriptase

Research into the chemistry of template-dependent nucleic acid biosynthesis, combined with modern techniques of molecular biology, has elucidated the life cycle and structure of the human immunodeficiency virus, the retrovirus that causes AIDS. A few years after the isolation of HIV, this research resulted in the development of drugs capable of prolonging the lives of people infected by HIV.

The first drug to be approved for clinical use was AZT, a structural analog of deoxythymidine. AZT was first synthesized in 1964 by Jerome P. Horwitz. It failed as an anticancer drug (the purpose for which it was made), but in 1985 it was found to be a useful treatment for AIDS. AZT is taken up by T lymphocytes, immune system cells that are particularly vulnerable to

HIV infection, and converted to AZT triphosphate. (AZT triphosphate taken directly would be ineffective because it cannot cross the plasma membrane.) HIV's reverse transcriptase has a higher affinity for AZT triphosphate than for dTTP, and binding of AZT triphosphate to this enzyme competitively inhibits dTTP binding. When AZT is added to the 3' end of the growing DNA strand, lack of a 3' hydroxyl means that the DNA strand is terminated prematurely and viral DNA synthesis grinds to a halt.

AZT triphosphate is not as toxic to the T lymphocytes themselves because *cellular* DNA polymerases have a lower affinity for this compound than for dTTP. At concentrations of 1 to 5 μM , AZT affects HIV reverse transcription but not most cellular DNA replication. Unfortunately, AZT seems to be toxic to the bone marrow cells that are the progenitors of erythrocytes, and many individuals taking AZT develop anemia. AZT can increase the survival time of people with advanced AIDS by about a year, and it delays the onset of AIDS in those who are still in the early stages of HIV infection. Some other AIDS drugs, such as dideoxyinosine (DDI), have a similar mechanism of action. Newer drugs target and inactivate the HIV protease. Because of the high error rate of HIV reverse transcriptase and the resulting rapid evolution of HIV, the most effective treatments of HIV infection use a combination of drugs directed at both the protease and the reverse transcriptase.

1090 RNA Metabolism **FIGURE 26-37 Introns that move: homing and retrohoming.** Certain introns include a gene (shown in red) for enzymes that promote homing (certain group I introns) or retrohoming (certain group II introns). (a) The gene in the spliced intron is bound by a ribosome and translated. Group I homing introns specify a site-specific endonuclease, called a homing endonuclease. Group II retrohoming introns specify a protein with both endonuclease and reverse transcriptase activities (not shown here). (b) Homing. Allele a of a gene X containing a group I homing intron is present in a cell containing allele b of the same gene, which lacks the intron. The homing endonuclease produced by a cleaves b at the position corresponding to the intron in a, and double-strand break repair (recombination with allele a; see Fig. 25-35) then creates a new copy of the intron in b. (c) Retrohoming. Allele a of gene Y contains a retrohoming group II intron; allele b lacks the intron. The spliced intron inserts itself into the coding strand of b in a reaction that is the reverse of the splicing that excised the intron from the primary transcript (see Fig. 26-15), except that here the insertion is into DNA rather than RNA. The noncoding DNA strand of b is then cleaved by the intron-encoded endonuclease/reverse transcriptase. This same enzyme uses the inserted RNA as a template to synthesize a complementary DNA strand. The RNA is then degraded by cellular ribonucleases and replaced with DNA. This sequence usually has the form T_xG_y in one strand and C_xA_y in the complementary strand, where x and y are typically in the range of 1 to 4 (p. 984). Telomeres vary in length from a few dozen base pairs in some ciliated protozoans to tens of thousands of base pairs in mammals. The TG strand is longer than its complement, leaving a region of single-stranded DNA of up to a few hundred nucleotides at the 3' end. The ends of a linear chromosome are not readily replicated by cellular DNA polymerases. DNA replication requires a template and primer, and beyond the end of a linear DNA molecule no template is available for the pairing of an RNA primer. Without a special mechanism for replicating the ends, chromosomes would be shortened somewhat in each cell generation. The enzyme telomerase, discovered by Carol Greider and Elizabeth Blackburn, solves this problem by adding telomeres to chromosome ends. Elizabeth Blackburn Carol Greider The discovery and purification of this enzyme provided

insight into a reaction mechanism that is remarkable and unprecedented. Telomerase, like some other (a) Production of homing endonuclease Group | intron » DNA for gene X, n allele a | transcription S S Primary a transcript splicing Spliced group | . intron translation Gene X product Homing endonuclease (b) Homing . enzymes described in this chapter, contains both RNA and protein components. The RNA component is about 150 nucleotides long and contains about 1.5 copies of the appropriate C,A,, telomere repeat. This region of the RNA acts as a template for synthesis of the T,G, strand of the telomere. Telomerase thereby acts as a cellular reverse transcriptase that provides the active site for RNA-dependent DNA synthesis. Unlike retroviral reverse transcriptases, telomerase carries only a small segment of RNA that it carries within itself. Telomere synthesis requires the 3' end of a chromosome as primer and proceeds in the usual 5'—> 3' direction. Having synthesized one copy of the repeat, the enzyme repositions to resume extension of the telomere (Fig. 26-38a). Telomerase _ GTTG3' 26.3 RNA-Dependent Synthesis of RNAand DNA 1091 After extension of the T,G, strand by telomerase, the complementary C,A,, strand is synthesized by cellular DNA polymerases, starting with an RNA primer (see Fig. 25-12). The single-stranded region is protected by specific binding proteins in many lower eukaryotes, especially those species with telomeres of less than a few hundred base pairs. In higher eukaryotes (including mammals) with telomeres many thousands of base pairs long, the single-stranded end is sequestered in a specialized structure called a T loop (Fig. 26—38b). The single-stranded end is folded back and paired with its complement in the double-stranded portion of the telomere. The formation of a T loop involves invasion of the 3' end of the telomere's single strand into the duplex CA strand TG strand Telomere duplex DNA-binding proteins TRF1 and TRF2 = (b) = 31 5' AACCCC dGTP, dTTP á AA ccc CA =) N = 35 PP; erTeeserres) 3 AAGE 5' SNA C CCGA =) € = a ;' \ Žž 5' Telomerase dissociates. O Telomere duplex DNA-binding proteins (a) TRF1 and TRF2 The single-stranded part of the telomere end is protected by telomere-binding proteins. internal template RNA of telomerase binds to and basepairs with the TG primer (T,G,) of DNA. Telomerase adds more T and G residues to the TG primer, then repositions the internal

template RNA to allow the addition of more T and G residues that generate the TG strand of the telomere. The complementary strand is synthesized by cellular DNA polymerases after priming by an RNA primase. (b) Proposed structure of T loops in telomeres. The single-stranded tail synthesized by telomerase is folded back and paired with its complement in the duplex portion of the telomere. The telomere is bound by several telomere-binding proteins, including TRF1 and TRF2 (telomere repeat binding factors). (c) Electron micrograph of a T loop at the end of a chromosome isolated from a mouse hepatocyte. The bar at the bottom of the micrograph represents a length of 5,000 bp.

1092 RNA Metabolism DNA, perhaps by a mechanism similar to the initiation of homologous genetic recombination (see Fig. 25-35). In mammals, the looped DNA is bound by two proteins, TRF1 and TRF2, with the latter protein involved in formation of the T loop. T loops protect the 3' ends of chromosomes, making them inaccessible to nucleases and the enzymes that repair double-strand breaks. In protozoans (such as *Tetrahymena*), loss of telomerase activity results in a gradual shortening of telomeres with each cell division, ultimately leading to the death of the cell line. A similar link between telomere length and cell senescence (cessation of cell division) has been observed in humans. In germ-line cells, which contain telomerase activity, telomere lengths are maintained; in somatic cells, which lack telomerase, they are not. There is a linear, inverse relationship between the length of telomeres in cultured fibroblasts and the age of the individual from whom the fibroblasts were taken: telomeres in human somatic cells gradually shorten as an individual ages. If the telomerase reverse transcriptase is introduced into human somatic cells in vitro, telomerase activity is restored and the cellular life span increases markedly. Is the gradual shortening of telomeres a key to the aging process? Is our natural life span determined by the length of the telomeres we are born with? Further research in this area should yield some fascinating insights.

Some Viral RNAs Are Replicated by RNA-Dependent RNA Polymerase Some *E. coli* bacteriophages, including ϕ 2, MS2, R17, and QB, as well as some eukaryotic viruses (including influenza and Sindbis viruses, the latter associated with a form of encephalitis) have RNA genomes. The singlestranded RNA chromosomes of these viruses, which also function as mRNAs for the synthesis of viral proteins, are replicated in the host cell by an RNA-dependent RNA polymerase (RNA replicase). All RNA viruses—with the exception of retroviruses—must encode a protein with RNA-dependent RNA polymerase activity, because the host cells do not possess this enzyme. The RNA replicase of most RNA bacteriophages has a molecular weight of $\sim 210,000$ and consists of four subunits. One subunit (M, 65,000) is the product of the replicase gene encoded by the viral RNA and has the active site for replication. The other three subunits are host proteins normally involved in host-cell protein synthesis: the *E. coli* elongation factors Tu (M, 45,000) and Ts (M, 34,000) (which ferry amino acyl-tRNAs to the ribosomes) and the

protein S1 (an integral part of the 30S ribosomal subunit). These three host proteins may help the RNA replicase locate and bind to the 3' ends of the viral RNAs. The RNA replicase isolated from Q ϕ -infected *E. coli* cells catalyzes the formation of an RNA complementary to the viral RNA, in a reaction equivalent to that catalyzed by DNA-dependent RNA polymerases. New RNA strand synthesis proceeds in the 5'—3' direction by a chemical mechanism identical to that used in all other nucleic acid synthetic reactions that require a template. RNA replicase requires RNA as its template and will not function with DNA. It lacks a separate proofreading endonuclease activity and has an error rate similar to that of RNA polymerase. Unlike the DNA and RNA polymerases, RNA replicases are specific for the RNA of their own virus; the RNAs of the host cell are generally not replicated. This explains how RNA viruses are preferentially replicated in the host cell, which contains many other types of RNA.

RNA Synthesis Offers Important Clues to Biochemical Evolution

The extraordinary complexity and order that distinguish living from inanimate systems are key manifestations of fundamental life processes. Maintaining the living state requires that selected chemical transformations occur very rapidly—especially those that use environmental energy sources and synthesize elaborate or specialized cellular macromolecules. Life depends on powerful and selective catalysts—enzymes—and on informational systems capable of both securely storing the blueprint for these enzymes and accurately reproducing it from generation to generation. Chromosomes encode the blueprint not only for the cell but for the enzymes that construct and maintain it as the cell. The parallel demands for information and catalysis present a classic conundrum: what came first, the information needed to specify structure or the enzymes needed to maintain and transmit the information? The unveiling of the structural and functional complexity of RNA led Carl Woese, Francis Crick, and Leslie Orgel to propose in the 1960s that this macromolecule might serve as both information carrier and catalyst. The discovery of catalytic RNAs took this proposal from conjecture to hypothesis and has led to widespread speculation that an “RNA world” might have been important in the transition from Leslie Orgel, 1927-2007

prebiotic chemistry to life (see Fig. 1-36). The parent of all life on this planet, in the sense that it could reproduce itself across the generations from the origin of life to the present, might have been a self-replicating RNA or a polymer with equivalent chemical characteristics. How might a self-replicating polymer come to be? How might it maintain itself in an environment where the precursors for polymer synthesis are scarce? How could evolution progress from such a polymer to the modern DNA-protein world? These difficult questions can be addressed by careful experimentation, providing clues about how life on Earth began and evolved. The probable origin of purine and pyrimidine bases is suggested by experiments designed to test hypotheses about prebiotic chemistry (pp. 33-34). Beginning with simple molecules thought to be present in the early atmosphere (CH_4 , NH_3 , H_2O , H_2), electrical discharges such as lightning generate, first, more reactive molecules such as HCN and aldehydes, then an array of amino acids and organic acids (see Fig. 1-34). When molecules such as HCN become abundant, purine and pyrimidine bases are synthesized in detectable amounts. Remarkably, a concentrated solution of ammonium cyanide, refluxed for a few days, generates adenine in yields of up to 0.5% (Fig. 26-39). Adenine may well have been the first and most abundant nucleotide constituent to appear on Earth. Intriguingly, most enzyme cofactors contain adenosine as part of their structure, although it plays no direct role in the cofactor function (see Fig. 8-38). This may suggest an evolutionary relationship. Based on the simple synthesis of adenine from cyanide, adenine may simply have been abundant and available. The RNA world hypothesis requires a nucleotide polymer to reproduce itself. Can a ribozyme bring about its own synthesis in a template-directed manner? Researchers are getting closer to finding such a ribozyme or ribozyme system. For example, Gerald Joyce and colleagues, in 2009, reported on the first set of two ribozymes that could cross-catalyze each other's formation (Fig. 26-40). One ribozyme, E, catalyzes the joining of two oligonucleotides (A' and B') to create a second and complementary ribozyme called E' . E' could then catalyze the joining of two other oligonucleotides (A and B) to form another molecule of E. In this system, the formation of E and E' was templated, and the amounts grew exponentially as long as substrates were available and proteins

were absent. The system evolved so that more efficient enzymes appeared in the population. FIGURE 26-39 Possible prebiotic synthesis of adenine from ammonium cyanide. Adenine is derived from five molecules of cyanide, denoted by shading.

26.3 RNA-Dependent Synthesis of RNA and DNA

1093 A more general RNA-polymerase-like ribozyme was described in 2011 by Philipp Holliger and colleagues. Indeed, the pace of discovery in this field is accelerating. A self-replicating polymer would quickly use up available supplies of precursors provided by the relatively slow processes of prebiotic chemistry. Thus, from an early stage in evolution, metabolic pathways would be required to generate precursors efficiently, with the synthesis of precursors presumably catalyzed by ribozymes. The extant ribozymes found in nature have a limited repertoire of catalytic functions, and of the ribozymes that may once have existed, no trace is left. To explore the RNA world hypothesis more deeply, we need to know whether RNA has the potential to catalyze the many different reactions needed in a primitive system of metabolic pathways. The search for RNAs with new catalytic functions has been aided by the development of a method that rapidly searches pools of random polymers of RNA and extracts those with particular activities: SELEX is nothing less than accelerated evolution in a test tube (Box 26-3). It has been used to generate RNA molecules that bind to amino acids, organic dyes, nucleotides, cyanocobalamin, and other molecules. Researchers have isolated ribozymes that catalyze ester and amide bond formation, S_N2 reactions, metallation of (addition of metal ions to) porphyrins, and carbon-carbon bond formation. The evolution of enzymatic cofactors with nucleotide “handles” that facilitate their binding to ribozymes might have further expanded the repertoire of chemical processes available to primitive metabolic systems. As we shall see in the next chapter, some natural RNA molecules catalyze the formation of peptide bonds, offering an idea of how the RNA world might have been transformed by the greater catalytic potential of proteins. The synthesis of proteins would have been a major event in the evolution of the RNA world but would also have hastened its demise. The information-carrying role of RNA may have passed to DNA because DNA is chemically more stable. RNA replicase and reverse transcriptase may be modern versions of enzymes that once played important roles in making the transition to the modern DNA-based system. The RNA world hypothesis is

now supported by at least five lines of evidence. First, RNA catalysts exist. RNA thus clearly has the capacity to both store information and catalyze reactions. Second, the wide range of reactions for which RNA catalysts have been developed is sufficient to form the basis of a primordial metabolic system. Third, there are numerous extant RNAs that are likely vestiges of an RNA world, including ribozymes, retroviruses, RNA viruses, and retrotransposons. Fourth, an RNA catalyst is responsible for the synthesis of proteins (Chapter 27). Finally, RNA catalysts with a capacity for self-replication are coming to light in the laboratory. An active field of investigation—prebiotic chemistry (not described here)—is revealing

1094 RNA Metabolism (a) A B i A B noa E' E' E J E' IN E E . —/ Pe

FIGURE 26-40 Self-sustained replication of an RNA enzyme. This system has many of the properties of a living system. The RNA molecules incorporate information and catalytic function, and the reactions produce an exponential increase in the product RNAs. When variants of the RNA substrates are introduced, the system undergoes natural selection such that the best replicators come to dominate the population. (a) The reaction scheme is outlined. Oligoribonucleotides A and B anneal to ribozyme E' and are ligated catalytically to form ribozyme E. The joining of oligoribonucleotides A and B to ribozyme E' is catalyzed by ribozyme E. The levels of E and E' grow exponentially, with a doubling time of about one hour at 42°C, as long as there is a supply of the precursors A, B, A', and B'. (b) The ligation reaction involves attack of the 3' OH of one oligoribonucleotide on the α-phosphate of the 5'-triphosphate of the other oligoribonucleotide. Pyrophosphate is released. Base pairing of the substrates with the ribozyme plays a key role in aligning the substrates for the reaction. These elements continue to make major contributions to the evolution of their hosts. Although the RNA world remains a hypothesis, with many gaps yet to be explained, experimental evidence supports a growing list of its key elements. Further experimentation should increase our understanding. Important clues to the puzzle will be found in the workings of fundamental chemistry, in living cells, and perhaps on other planets. Meanwhile,

the extant RNA universe continues to expand (Box 26-4).
SUMMARY 26.3 RNA-Dependent Synthesis of RNA and DNA >
 RNA-dependent DNA polymerases, also called reverse transcriptases, were first discovered in retroviruses, which must convert their RNA

BOX 26-3 METHODS with New Functions SELEX

(systematic evolution of ligands by exponential enrichment) is used to generate aptamers, oligonucleotides selected to tightly bind a specific molecular target. The process is generally automated to allow rapid identification of one or more aptamers with the desired binding specificity. Figure 1 illustrates how SELEX is used to select an RNA species that binds tightly to ATP. In step @, a random mixture of RNA polymers is subjected to “unnatural selection” by passing it through a resin to which ATP is attached. The practical limit for the complexity of an RNA mixture in SELEX is about 10^8 different sequences, which allows for the complete randomization of 25 nucleotides ($4^8 = 10^8$). For longer RNAs, the RNA pool used to initiate the search does not include all possible sequences. @ RNA polymers that pass through the column are discarded; © those that bind to ATP are washed from the column with salt solution and collected. @ The collected RNA polymers are amplified by reverse transcriptase to make many DNA complements to the selected RNAs; then an RNA polymerase makes many RNA complements of the resulting DNA molecules. @ This new pool of RNA is subjected to the same selection procedure, and the cycle is repeated a dozen or more times. At the end, only a few aptamers—in this case, RNA sequences with considerable affinity for ATP—remain. 10^8 random RNA sequences ATP coupled to resin RNA sequences enriched for ATP-binding function C4) amplify RNA sequences RNA sequences that bind ATP that do not bind ATP (discard) FIGURE 1 The SELEX procedure. 26.3 RNA-Dependent Synthesis of RNA and DNA 1095 The SELEX Method for Generating RNA Polymers Critical sequence features of an RNA aptamer that binds ATP are shown in Figure 2; molecules with this general structure bind ATP (and other adenosine nucleotides) with $K_a < 50 \mu\text{M}$. Figure 3 presents the three-dimensional structure of a 36 nucleotide RNA aptamer (shown as a complex with AMP) generated by SELEX. This RNA has the backbone structure shown in Figure 2. In addition to its use in exploring the potential functionality of RNA, SELEX has an important practical side in identifying short RNAs with pharmaceutical uses. Finding an aptamer that binds specifically to every potential therapeutic target may be impossible, but the capacity of SELEX to rapidly select and amplify a specific oligonucleotide sequence from a highly complex pool of sequences

makes this a promising approach for the generation of new therapies. For example, one could select an RNA that binds tightly to a receptor protein prominent in the plasma membrane of cells in a particular cancerous tumor. Blocking the activity of the receptor, or targeting a toxin to the tumor cells by attaching it to the aptamer, would kill the cells. SELEX also has been used to select DNA aptamers that detect anthrax spores. Many other promising applications are under development. E “TOIL 3! "GE FIGURE 2 RNA aptamer that binds ATP. The shaded nucleotides are those required for the binding activity. GGAAGAAACUG FIGURE 3 (Derived from PDB ID 1IRAW) RNA aptamer bound to AMP. SELEX (systematic evolution of ligands by *exponential* enrichment) is used to generate **aptamers**, oligonucleotides selected to tightly bind a specific molecular target. The process is generally automated to allow rapid identification of one or more aptamers with the desired binding specificity.

Figure 1 illustrates how SELEX is used to select an RNA species that binds tightly to ATP. In step ①, a random mixture of RNA polymers is subjected to “unnatural selection” by passing it through a resin to which ATP is attached. The practical limit for the complexity of an RNA mixture in SELEX is about 10^{15} different sequences, which allows for the complete randomization of 25 nucleotides ($4^{25} = 10^{15}$). For longer RNAs, the RNA pool used to initiate the search does not include all possible sequences. ② RNA polymers that pass through the column are discarded; ③ those that bind to ATP are washed from the column with salt solution and collected. ④ The collected RNA polymers are amplified by reverse transcriptase to make many DNA complements to the selected RNAs; then an RNA polymerase makes many RNA complements of the resulting DNA molecules. ⑤ This new pool of RNA is subjected to the same selection procedure, and the cycle is repeated a dozen or more times. At the end, only a few aptamers—in this case, RNA sequences with considerable affinity for ATP—remain.

FIGURE 1 The SELEX procedure.

Critical sequence features of an RNA aptamer that binds ATP are shown in Figure 2; molecules with this general structure bind ATP (and other adenosine nucleotides) with $K_d < 50 \mu\text{M}$. Figure 3 presents the three-dimensional structure of a 36 nucleotide RNA aptamer (shown as a complex with AMP) generated by SELEX. This RNA has the backbone structure shown in Figure 2.

In addition to its use in exploring the potential functionality of RNA, SELEX has an important practical side in identifying short RNAs with pharmaceutical uses. Finding an aptamer that binds specifically to every potential therapeutic target may be impossible, but the capacity of SELEX to rapidly select and amplify a specific oligonucleotide sequence from a highly complex pool of sequences makes this a promising approach for the generation of new therapies. For example, one could select an RNA that binds tightly to a receptor protein prominent in the plasma membrane of cells in a particular cancerous tumor. Blocking the activity of the receptor, or targeting a toxin to the tumor cells by attaching it to the aptamer, would kill the cells. SELEX also has been used to select DNA aptamers that detect anthrax spores. Many other promising applications are under development. ■

FIGURE 2 RNA aptamer that binds ATP. The shaded nucleotides are those required for the binding activity.

FIGURE 3 (Derived from PDB ID 1RAW) RNA aptamer bound to AMP. The bases of the conserved nucleotides (forming the binding pocket) are white; the bound AMP is red.

1096 RNA Metabolism Current estimates for the number of genes in the human genome, and in many other genomes, are mentioned in multiple places throughout this text. The estimates presume that scientists know a gene when they see it, based on our current understanding of DNA, RNA, and proteins. Is the presumption correct? As noted in Chapter 9, less than 2% of the human genome seems to encode proteins. Even when introns | isolate RNA Various RNA-binding proteins — remove proteins immunoprecipitate remove proteins make cDNA (primer and reverse transcriptase) covalently link biotin (B) to cap B B — a B — se degrade RNA not paired to cDNA with RNase | B e ee B PE B a B p La = isolate full-length cDNA linked to biotin B BOX 26-4 An Expanding RNA Universe Filled with TUF RNAs are factored in, one might expect only a tiny fraction of the genome to be transcribed into RNA, mostly mRNA to encode those proteins. The remainder of the genome has sometimes been referred to as junk DNA. The “junk” moniker simply reflects our ignorance, which is slowly giving way to the realization that most of the genome is fully functional. In an effort to better map the boundaries of the human transcriptome, researchers have invented new tools to determine with higher accuracy which genomic sequences are transcribed into RNA. The answers are surprising. Much more of our genome is transcribed into RNA than anyone supposed. Much of this RNA seems not to encode proteins. Much of it lacks some of the structures (for example, the 3' poly(A) tail) that characterize mRNA. So what is this RNA doing? Most of the methods for looking into this matter fall into two broad categories: cDNA cloning and microarrays. The creation of a cDNA library to study the genes transcribed in a particular eukaryotic genome is described in Chapter 9 (see Fig. 9-14). However, the classical methods for generating cDNA often lead to the cloning of only part of the sequence of a given transcript. Because reverse transcriptase may stall at regions of secondary structure in mRNA, or may simply dissociate, often 20% or less of the clones in a cDNA library are fulllength DNAs. This makes it difficult to use the library to map transcription start sites (TSSs) and to study the part of a gene that encodes the amino-terminal sequence of a protein. One of the many approaches developed to overcome this problem is illustrated in Figure 1. Such refinements in technology have resulted in the

creation of cDNA libraries in which more than 95% of the clones are full-length, providing an enriched source of information about cellular RNAs. However, cDNAs are generally created from RNA transcripts that have poly(A) tails. The use of microarrays, coupled to methods of cDNA preparation that do not rely on poly(A) tails (Fig. 2), has revealed that much of the RNA in eukaryotic cells lacks the common end structures. A complete picture has not yet emerged, but some conclusions are already clear. If one excludes the repetitive sequences (transposons, for example) that can make up half of a mammalian genome, at least

FIGURE 1 A strategy for cloning full-length cDNAs. A pool of mRNAs is isolated from a tissue sample. In some cases, mRNAs bound by a particular protein may be targeted by immunoprecipitating the protein and isolating the associated mRNAs. Biotin (B) is covalently attached to the 5' ends of the mRNAs, making use of unique features of the 5' cap. A poly(dT) primer (purple) is used to prime reverse transcription of the mRNAs. RNase H degrades RNA that is not part of a DNA-RNA hybrid and thus destroys the incomplete cDNA-RNA pairs. The full-length cDNA-RNA hybrids are collected with streptavidin beads (which bind biotin), converted to duplex DNA, and cloned.

40%—and perhaps the vast majority—of the remaining genomic DNA is transcribed into RNA. There seem to be more RNAs lacking poly(A) tails than RNAs with them. Much of this RNA is not transported to the cytoplasm but remains exclusively in the nucleus. Many segments of the genome are transcribed on both strands; one transcript is the complement of the other, a relationship referred to as antisense. Many of the antisense RNAs may be involved in regulation of the RNAs with which they pair. Many RNAs are produced in only one or a few tissues, and new transcripts are discovered every time a new tissue source is analyzed. Thus, the complete transcriptome has not yet been defined for any organism. Most important, many of the novel (a) Genome sequence AAGCTTATGGTCCCTAATCATAACGTAGCTTCCCTAATCTGA Oligos synthesized for microarray: GCTTATGGTCCCTAATCATAACGTATGGTCCCTAATCATAACGTAGCTTC 26.3 RNA-Dependent Synthesis of RNA and DNA 1097 thought, and the number of known protein-encoding genes may soon increase. However, the function of most of the newly discovered transcripts is unknown, and they are simply called TUFs (transcripts of unknown function). This new RNA universe is a frontier that promises further insights into the workings of eukaryotic cells and perhaps a new glimpse of our origins in the RNA world of the distant past.

CCTAATCATAACGTAGCTTCCCTAA RNAs are transcribed from genomic segments, such as those illustrated in Figure 9-15, that share synteny in more than one organism. This evolutionary conservation strongly suggests that these RNAs have an important function. Some of the novel RNAs are snoRNAs, snRNAs, or miRNAs, types of RNA recognized only in the past two decades. New TSS sequences are being (b) discovered. New classes of RNA molecules are being defined. New patterns of alternative splicing are being elucidated. And all of these findings are challenging our definitions of a gene. In the mouse Nuclear RNA Cytosolic RNA and human genomes, even the familiar protein-encoding mRNA transcripts may be much more numerous than initially reported. poly(A)- poly(A) poly(A)~ FIGURE 2 Defining the transcriptome with microarrays. | | | a) Tiled microarrays are synthesized, representing G Y y P E Make cDNA Make cDNA Make cDNA Make cDNA the nonrepetitive parts of the genome. In a tiled array, the successive oligonucleotides in the individual spots overlap in

sequence, so that each nucleotide (such as the T shown in blue) is represented multiple times. (b) A tissue sample is fractionated to separate nuclear and cytoplasmic samples, and RNA is isolated from each. The RNA containing poly(A) tails is separated from RNA lacking the tails (by passing the RNA over a column with bound poly(dT)). RNA with a poly(A) tail is converted to cDNA, using methods described in Figure 1. RNA lacking a poly(A) tail is converted to cDNA by using primers with randomized sequences. The resulting DNA fragments do not correspond in length precisely to the RNAs from which they are derived, but the overall DNA pool includes most of the sequences present in the original RNAs. The cDNA samples are then labeled and used to probe the microarrays. The signals from the microarrays define the sequences that were transcribed into RNA. Problems 1. RNA Polymerase (a) How long would it take for the *E. coli* RNA polymerase to synthesize the primary transcript for the *E. coli* genes encoding the enzymes for lactose metabolism (the 5,300 bp *lac* operon, considered in Chapter 28)? (b) How far along the DNA would the transcription “bubble” formed by RNA polymerase move in 10 seconds? 2. Error Correction by RNA Polymerases DNA polymerases are capable of editing and error correction, whereas the capacity for error correction in RNA polymerases seems to be quite limited. Given that a single base error in either replication or transcription can lead to an error in protein synthesis, suggest a possible biological explanation for this difference. 3. RNA Posttranscriptional Processing Predict the likely effects of a mutation in the sequence (5')AAUAAA in a eukaryotic mRNA transcript. 4. Coding versus Template Strands The RNA genome of phage QB is the nontemplate strand, or coding strand, and when introduced into the cell, it functions as an mRNA. Suppose the RNA replicase of phage Q8 synthesized primarily template-strand RNA and uniquely incorporated this, rather than nontemplate strands, into the viral particles. What would be the fate of the template strands when they entered a new cell? What enzyme would have to be included in the viral particles for successful invasion of a host cell? 5. Transcription The gene encoding the *E. coli* enzyme β -galactosidase begins with the sequence ATGACCATGATTACG. What is the sequence of the RNA transcript specified by this part of the gene? 6. The Chemistry of Nucleic Acid Biosynthesis Describe three properties common to the reactions catalyzed by DNA polymerase, RNA polymerase, reverse transcriptase, and RNA replicase. How is the enzyme polynucleotide phosphorylase similar to and different from these four enzymes? 7. RNA Splicing What is the minimum number of transesterification reactions needed to splice an intron from an mRNA transcript? Explain. 8. RNA Processing If the splicing of mRNA in a vertebrate cell is blocked, the rRNA

modification reactions are also blocked. Suggest a reason for this. 9. RNA Genomes The RNA viruses have relatively small genomes. For example, the single-stranded RNAs of retroviruses have about 10,000 nucleotides and the QB RNA is only 4,220 nucleotides long. Given the properties of reverse transcriptase and RNA replicase described in this chapter, can you suggest a reason for the small size of these viral genomes? 10. Screening RNAs by SELEX The practical limit for the number of different RNA sequences that can be screened in a SELEX experiment is 10^9 . (a) Suppose you are working with oligonucleotides 32 nucleotides long. How many sequences exist in a randomized pool containing every sequence possible?

1100 RNA Metabolism (b) What percentage of these can be screened in a SELEX experiment? (c) Suppose you wish to select an RNA molecule that catalyzes the hydrolysis of a particular ester. From what you know about catalysis, propose a SELEX strategy that might allow you to select the appropriate catalyst.

11. Slow Death The death cap mushroom, *Amanita phalloides*, contains several dangerous substances, including the lethal α -amanitin. This toxin blocks RNA elongation in consumers of the mushroom by binding to eukaryotic RNA polymerase II with very high affinity; it is deadly in concentrations as low as 1078 m. The initial reaction to ingestion of the mushroom is gastrointestinal distress (caused by some of the other toxins). These symptoms disappear, but about 48 hours later, the mushroom-eater dies, usually from liver dysfunction. Speculate on why it takes this long for α -amanitin to kill.

12. Detection of Rifampicin-Resistant Strains of Tuberculosis Rifampicin is an important antibiotic used to treat tuberculosis and other mycobacterial diseases. Some strains of *Mycobacterium tuberculosis*, the causative agent of tuberculosis, are resistant to rifampicin. These strains become resistant through mutations that alter the *rpoB* gene, which encodes the B subunit of the RNA polymerase. Rifampicin cannot bind to the mutant RNA polymerase and so is unable to block the initiation of transcription. DNA sequences from a large number of rifampicin-resistant *M. tuberculosis* strains have been found to have mutations in a specific 69 bp region of *rpoB*. One well-characterized rifampicin-resistant strain has a single base pair alteration in *rpoB* that results in a His residue being replaced by an Asp residue in the B subunit. (a) Based on your knowledge of protein chemistry, suggest a technique that would allow detection of the rifampicin-resistant strain containing this particular mutant protein. (b) Based on your knowledge of nucleic acid chemistry, suggest a technique to identify the mutant form of *rpoB*.

Using the Web 13. The Ribonuclease Gene Human pancreatic ribonuclease has 128 amino acid residues. (a) What is the minimum number of nucleotide pairs required to code for this protein? (b) The mRNA expressed in human pancreatic cells was copied with reverse transcriptase to create a "library" of human DNA. The sequence of the mRNA coding for human pancreatic ribonuclease was determined by sequencing the complementary DNA (cDNA) from this library that included an open reading frame

for the protein. Use the Entrez database system (www.ncbi.nlm.nih.gov/Entrez) to find the published sequence of this mRNA (search the CoreNucleotide database for accession number D26129). What is the length of this mRNA? (c) How can you account for the discrepancy between the size you calculated in (a) and the actual length of the mRNA? Data Analysis Problem 14.

A Case of RNA Editing The AMPA (α-amino-3-hydroxy-5methyl-4-isoxazolepropionic acid) receptor is an important component of the human nervous system. It is present in several forms, in different neurons, and some of this variety results from posttranscriptional modification. This problem explores research on the mechanism of this RNA editing. An initial report by Sommer and coauthors (1991) looked at the sequence encoding a key Arg residue in the AMPA receptor. The sequence of the cDNA (see Fig. 9-14) for the AMPA receptor showed a CGG (Arg; see Fig. 27—7) codon for this amino acid. Surprisingly, the genomic DNA showed a CAG (Gln) codon at this position. (a) Explain how this result is consistent with posttranscriptional modification of the AMPA receptor mRNA. Rueter and colleagues (1995) explored this mechanism in detail. They first developed an assay to differentiate between edited and unedited transcripts, based on the Sanger method of DNA sequencing (see Fig. 8-33). They modified the technique to determine whether the base in question was an A (as in CAG) or not. They designed two DNA primers based on the genomic DNA sequence of this region of the AMPA gene. These primers, and the genomic DNA sequence of the nontemplate strand for the relevant region of the AMPA receptor gene, are shown at the bottom of the page; the A residue that is edited is in red. To detect whether this A was present or had been edited to another base, Rueter and coworkers used the following procedure: 1. Prepared cDNA complementary to the mRNA, using primer 1, reverse transcriptase, (ATP, dGTP, dCTP, and dTTP. 2. Removed the mRNA. 3. Annealed ³²P-labeled primer 2 to the cDNA and reacted this with DNA polymerase, dGTP, dCTP, dTTP, and ddATP (dideoxy ATP; see Fig. 8-33). 4. Denatured the resulting duplexes and separated them with polyacrylamide gel electrophoresis (see Fig. 3-18). 5. Detected the ³²P-labeled DNA species with autoradiography. They found that edited mRNA produced a 22 nucleotide [³²P] DNA, whereas unedited mRNA produced a 19 nucleotide ³²P] DNA. (b) Using the sequences below, explain how the edited and unedited mRNAs

resulted in these different products. (5')

...GTCTCTGGTTTTCTTGGGTGCCTTTATGCAGCAAGGATGCGATATTTTCG

Primer 1: Primer 2: CGTTCCTACGCTATAAAGC GGTTC (5') (5')

CCTTGGGTGCCTTTA

Using the same procedure, to measure the fraction of transcripts edited under different conditions, the researchers found that extracts of cultured epithelial cells (a common cell line called HeLa) could edit the mRNA at a high level. To determine the nature of the editing machinery, they pretreated an active HeLa cell extract as described in the table and measured its ability to edit AMPA mRNA. Proteinase K degrades only proteins; micrococcal nuclease, only DNA.

Sample Pretreatment	% mRNA edited
1 None	18
2 Proteinase K	5
3 Heat to 65°C	3
4 Heat to 85°C	5
5 Micrococcal nuclease	17

(c) Use these data to argue that the editing machinery consists of protein. What is a key weakness in this argument? To determine the exact nature of the edited base, Rueter and colleagues used the following procedure:

1. Produced mRNA, using [a-³²P]ATP in the reaction mixture. . Edited the labeled mRNA by incubating with HeLa extract.
3. Hydrolyzed the edited mRNA to single nucleotide monophosphates with nuclease P1.
4. Separated the nucleotide monophosphates with thin-layer chromatography (TLC; see Fig. 10-25b).
5. Identified the resulting ³²P-labeled nucleotide monophosphates with autoradiography.

Data Analysis Problem 1101 In unedited mRNA, they found only [³²P]AMP; in edited mRNA, they found mostly [³²P]JAMP with some [³²P]IMP (inosine monophosphate; see Fig. 22-36).

(d) Why was it necessary to use [a-³²P]ATP rather than [B-³²P]ATP or [y-³²P]ATP in this experiment? (e) Why was it necessary to use [a-³²P]ATP rather than [a-³²P]GTP, [a-³²P]CTP, or [a-³²P]UTP? (f) How does the result exclude the possibility that the entire A nucleotide (sugar, base, and phosphate) was removed and replaced by an I nucleotide during the editing process? The researchers next edited mRNA that was labeled with [2,8-³H]ATP and repeated the above procedure. The only ³H-labeled mononucleotides produced were AMP and IMP. (g) How does this result exclude removal of the A base (leaving the sugar-phosphate backbone intact) followed by replacement with an I base as a mechanism of editing? What, then, is the most likely mechanism of editing in this case? (h) How does changing an A to an I residue in the mRNA explain the Gln to Arg change in protein sequence in the two forms of AMPA receptor protein? (Hint: See Fig. 27-8.)

Protein Metabolism 27.1 The Genetic Code 1103 27.2 Protein Synthesis 1113 27.3 Protein Targeting and Degradation 1139

pathways. A typical cell requires thousands of different proteins at any given moment. These must be synthesized in response to the cell's current needs, transported (targeted) to their appropriate cellular locations, and degraded when no longer needed. Many of the fundamental components and mechanisms utilized by the protein biosynthetic machinery are remarkably well conserved in all life-forms from bacteria to higher eukaryotes, indicating that they were present in the last universal common ancestor (LUCA) of all extant organisms. An understanding of protein synthesis, the most complex biosynthetic process, has been one of the greatest challenges in biochemistry. Eukaryotic protein synthesis involves more than 70 different ribosomal proteins; 20 or more enzymes to activate the amino acid precursors; a dozen or more auxiliary enzymes and other protein factors for the initiation, elongation, and termination of polypeptides; perhaps 100 additional enzymes for the final processing of different proteins; and 40 or more kinds of transfer and ribosomal RNAs. Overall, almost 300 different macromolecules cooperate to synthesize polypeptides. Many of these macromolecules are organized into the complex three-dimensional structure of the ribosome. To appreciate the central importance of protein synthesis, consider the cellular resources devoted to this process. Protein synthesis can account for up to 90% of the chemical energy used by a cell for all biosynthetic reactions. Every bacterial, archaeal, and eukaryotic cell contains from several to thousands of copies of many different proteins and RNAs. The 15,000 ribosomes, 100,000 molecules of protein synthesis—related protein factors and enzymes, and 200,000 tRNA molecules in a typical bacterial cell can account for more than 35% of the cell's dry weight. p roteins are the end products of most information Despite the great complexity of protein synthesis, proteins are made at exceedingly high rates. A polypeptide of 100 residues is synthesized in an *Escherichia coli* cell (at 37 °C) in about 5 seconds. Synthesis of the thousands of different proteins in a cell is tightly regulated, so that just enough copies are made to match the current metabolic circumstances. To maintain the appropriate mix and concentration of proteins, the targeting and degradative processes must keep pace with synthesis. Research is gradually

uncovering the finely coordinated cellular choreography that guides each protein to its proper cellular location and selectively degrades it when it is no longer required. The study of protein synthesis offers another important reward: a look at a world of RNA catalysts that may have existed before the dawn of life “as we know it.” Elucidation of the three-dimensional structures of ribosomes, beginning in the year 2000, has given us an increasingly detailed look at the mechanics of protein synthesis. It has also confirmed a hypothesis first put forward by Harry Noller two decades earlier: proteins are synthesized by a gigantic RNA enzyme!

27.1 The Genetic Code

Three major advances set the stage for our present knowledge of protein biosynthesis. First, in the early 1950s, Paul Zamecnik and his colleagues designed a set of experiments to investigate where in the cell proteins are synthesized. They injected radioactive amino acids into rats and, at different time intervals after the injection, removed the liver, homogenized it, fractionated the homogenate by centrifugation, and examined the subcellular fractions for the presence of radioactive protein. When hours or days were allowed to elapse after injection of the labeled amino acids, all the subcellular

1103 Harry Noller

1104 Protein Metabolism fractions contained labeled proteins. However, when only minutes had elapsed, labeled protein appeared only in a fraction containing small ribonucleoprotein particles. These particles, visible in animal tissues by electron microscopy, were therefore identified as the site of protein synthesis from amino acids and later were Paul Zamecnik, 1912-2009 named ribosomes (Fig. 27-1). The second key advance was made by Mahlon Hoagland and Zamecnik when they found that amino acids were “activated” when incubated with ATP and the cytosolic fraction of liver cells. The amino acids became attached to a heat-stable soluble RNA of the type that had been discovered and characterized by Robert Holley and later called transfer RNA (tRNA), to form aminoacyl-tRNAs. The enzymes that catalyze this process are the aminoacyl-tRNA synthetases. The third advance resulted from Francis Crick’s reasoning on how the genetic information encoded in the 4-letter language of nucleic acids could be translated into the 20-letter language of proteins. A small nucleic acid (perhaps RNA) could serve the role of an adaptor, one part of the adaptor molecule binding a specific amino acid and another part recognizing the nucleotide sequence encoding that amino acid in an mRNA (Fig. 27-2). This idea was soon verified. The tRNA adaptor “translates” the nucleotide sequence of an mRNA into the amino acid sequence of a polypeptide. The overall process of mRNA-guided protein synthesis is often referred to simply as translation. Ribosomes Cytosol

FIGURE 27-1 Ribosomes and endoplasmic reticulum. Electron micrograph and schematic drawing of a portion of a pancreatic cell, showing ribosomes attached to the outer (cytosolic) face of the endoplasmic reticulum (ER). The ribosomes are the numerous small dots bordering the parallel layers of membranes.

~\ Amino acid “Amino acid binding site Adaptor mRNA Nucleotide triplet coding for an amino acid

FIGURE 27-2 Crick’s adaptor hypothesis. Today we know that the amino acid is covalently bound at the 3’ end of atRNA molecule and that a specific nucleotide triplet elsewhere in the tRNA interacts with a particular triplet codon in mRNA through hydrogen bonding of complementary bases. These three developments soon led to recognition of the major stages of protein synthesis and ultimately to the elucidation of the genetic code that specifies each amino acid. The Genetic Code Was Cracked Using Artificial mRNA

Templates By the 1960s it was apparent that at least three nucleotide residues of DNA are necessary to encode each amino acid. The four code letters of DNA (A, T, G, and C) in groups of two can yield only $4^2 = 16$ different combinations, insufficient to encode 20 amino acids. Groups of three, however, yield $4^3 = 64$ different combinations. Several key properties of the genetic code were established in early genetic studies (Figs 27-3, 27-4).

Nonoverlapping A U A, C G A G U C, code 1 2 3 Overlapping

AUACGAGUC code 1 1 2 1 3 FIGURE 27-3 Overlapping versus

nonoverlapping genetic codes. In a nonoverlapping code, codons (numbered consecutively) do not share nucleotides. In an

overlapping code, some nucleotides in the mRNA are shared by

different codons. In a triplet code with maximum overlap, many

nucleotides, such as the third nucleotide from the left (A), are

shared by three codons. Note that in an overlapping code, the

triplet sequence of the first codon limits the possible sequences for

the second codon. A nonoverlapping code provides much more

flexibility in the triplet sequence of neighboring codons and

therefore in the possible amino acid sequences designated by the

code. The genetic code used in all living systems is now known to

be nonoverlapping.

Reading frame restored A codon is a triplet of nucleotides that codes for a specific amino acid. Translation occurs in such a way that these nucleotide triplets are read in a successive, nonoverlapping fashion. A specific first codon in the sequence establishes the reading frame, in which a new codon begins every three nucleotide residues. There is no punctuation between codons for successive amino acid residues. The amino acid sequence of a protein is defined by a linear sequence of contiguous triplets. In principle, any given single-stranded DNA or mRNA sequence has three possible reading frames. Each reading frame gives a different sequence of codons (Fig. 27-5), but only one is likely to encode a given protein. A key question remained: what were the three-letter code words for each amino acid? In 1961 Marshall Nirenberg and Heinrich Matthaei reported the first breakthrough. They incubated synthetic polyuridylylate, poly (U), with an *E. coli* extract, GTP, ATP, and a mixture of the 20 amino acids in 20 different tubes, each tube containing a different radioactively labeled amino acid. Because poly(U) mRNA is made up of many successive UUU triplets, it should promote the synthesis of a polypeptide containing only the amino acid encoded by the triplet UUU. A radioactive polypeptide was indeed formed in only one of the 20 tubes, the one containing radioactive phenylalanine. Nirenberg and Matthaei therefore concluded that the triplet codon UUU encodes phenylalanine. The same approach soon revealed that polycytidylylate, poly(C), Marshall Nirenberg 27.1 The Genetic Code 1105

FIGURE 27-4 The triplet, nonoverlapping code. Evidence for the general nature of the genetic code came from many types of experiments, including genetic experiments on the effects of deletion and insertion mutations. Inserting or deleting one base pair (shown here in the mRNA transcript) alters the sequence of triplets in a nonoverlapping code; all amino acids coded by the mRNA following the change are affected. Combining insertion and deletion mutations affects some amino acids but can eventually restore the correct amino acid sequence. Adding or subtracting three nucleotides (not shown) leaves the remaining triplets intact, providing evidence that a codon has three, rather than four or five, nucleotides. The triplet codons

shaded in gray are those transcribed from the original gene; codons shaded in blue are new codons resulting from the insertion or deletion mutations. encodes a polypeptide containing only proline (polyproline), and polyadenylate, poly(A), encodes polylysine. Polyguanylate did not generate any polypeptide in this experiment because it spontaneously forms tetraplexes (see Fig. 8-20d) that cannot be bound by ribosomes. The synthetic polynucleotides used in such experiments were prepared with polynucleotide phosphorylase (p. 1085), which catalyzes the formation of RNA polymers starting from ADP, UDP, CDP, and GDP. This enzyme, discovered by Severo Ochoa, requires no template and makes polymers with a base composition that directly reflects the relative concentrations of the nucleoside 5'-diphosphate precursors in the medium. If polynucleotide phosphorylase is presented with UDP only, it makes only poly(U). If it is presented with a mixture of five parts ADP and one part CDP, it makes a polymer in which about five-sixths of the residues are adenylate and one-sixth are cytidylate. This random polymer is likely to have many triplets of the sequence AAA, smaller numbers of AAC, ACA, and CAA triplets, relatively few ACC, CCA, and CAC triplets, and very few CCC triplets (Table 27-1). Using a variety of artificial mRNAs made by polynucleotide phosphorylase from different starting mixtures of ADP, GDP, UDP, and CDP, the Nirenberg and Ochoa groups soon identified the base compositions of the triplets coding for almost all the amino acids. Although these experiments revealed the base composition of the coding triplets, they usually could not reveal the sequence of the bases. KEY CONVENTION: Much of the following discussion deals with tRNAs. The amino acid specified by a tRNA is indicated by a superscript, such as tRNA[?] and the aminoacylated tRNA by a hyphenated name: alanyl-tRNA^{*} or Ala-tRNA^{*}. m

FIGURE 27-5 Reading frames in the genetic code. In a triplet, nonoverlapping code, all mRNAs have three potential reading frames, shaded here in different colors. The triplets, and hence the amino acids specified, are different in each reading frame.

1106 Protein Metabolism Incorporation of Amino Acids into Polypeptides in Response to Random Polymers of RNA

Observed Tentative assignment Expected frequency frequency of for nucleotide of incorporation incorporation composition of based on assignment Amino acid (Lys = 100) corresponding codon* (Lys = 100) Asparagine 24 AC 20 Glutamine 24 AC 20 Histidine 6 AC» 4 Lysine 100 AAA 100 Proline 0 ACs, CCC 4.8 Threonine 26 AC, ACo 24 Note: Presented here is a summary of data from one of the early experiments designed to elucidate the genetic code. A synthetic RNA containing only A and C residues in a 5:1 ratio directed polypeptide synthesis, and both the identity and the quantity of incorporated amino acids were determined. Based on the relative abundance of A and C residues in the synthetic RNA, and assigning the codon AAA (the most likely codon) a frequency of 100, there should be three different codons of composition A,C, each at a relative frequency of 20; three of composition AC,, each ata relative frequency of 4.0; and CCC at a relative frequency of 0.8. The CCC assignment was based on information derived from prior studies with poly(C). Where two tentative codon assignments are made, both are proposed to code for the same amino acid. *These designations of nucleotide composition contain no information on nucleotide sequence (except, of course, AAA and CCC). In 1964 Nirenberg and Philip Leder achieved another experimental breakthrough. Isolated *E. coli* ribosomes would bind a specific aminoacyl-tRNA in the presence of the corresponding synthetic polynucleotide messenger. For example, ribosomes incubated with poly(U) and phenylalanyl-tRNA^{TM*}® (Phe-tRNA^{TM*}) bind both RNAs, but if the ribosomes are incubated with poly(U) and some other aminoacyl-tRNA, the aminoacyl-tRNA is not bound, because it does not recognize the UUU triplets in poly(U) (Table 27-2). Even trinucleotides could promote specific binding of appropriate tRNAs, so these experiments could be carried out with chemically synthesized small oligonucleotides. With this technique researchers determined which aminoacyl-tRNA bound to 54 of the 64 possible triplet codons. For some codons, either no aminoacyl-tRNA or more than one would bind. Another method was needed to complete and confirm the entire genetic code. VIFAA Trinucleotides That Induce Specific Binding of Aminoacyl-tRNAs to Ribosomes Relative increase in “C-labeled aminoacyl-tRNA bound to ribosome*"

Trinucleotide Phe-tRNATM —Lys-tRNA'S Pro-tRNATM''' UUU 4.6 0 0
 AAA 0 TT 0 GCG 0 0 3.1 Source: Modified from Nirenberg, M. &
 Leder, P. (1964) RNA code words and protein synthesis. Science
 145, 1399. *Each number represents the factor by which the
 amount of bound **C increased when the indicated trinucleotide
 was present, relative to a control with no trinucleotide. At about
 this time, a complementary approach was provided by H. Gobind
 Khorana, who developed chemical methods to synthesize
 polyribonucleotides with defined, repeating sequences of two to
 four bases. The polypeptides produced by these mRNAs had one or
 a few amino acids in repeating pat| terns. These patterns, when
 combined with information from the random polymers used by
 Nirenberg and colleagues, permitted unambiguous codon
 assignments. The copolymer (AC),,, for example, has alternating
 ACA and CAC codons: ACACACACACACA. The polypeptide
 synthesized on this messenger contained equal amounts of
 threonine and histidine. Given that a histidine codon has one A and
 two Cs (Table 27-1), CAC must code for histidine and ACA for
 threonine. Consolidation of the results from many experiments
 permitted the assignment of 61 of the 64 possible codons. The other
 three were identified as termination codons, in part because they
 disrupted amino acid coding patterns when they occurred in a
 synthetic RNA polymer (Fig. 27-6). Meanings for all the triplet
 codons (tabulated in Fig. 27-7) were established by 1966 and have
 been verified in many different ways. The cracking of the genetic
 code is regarded as one of the most important scientific discoveries
 of the twentieth century. Codons are the key to the translation of
 genetic information, directing the synthesis of specific proteins. The
 reading frame is set when translation of an mRNA H. Gobind
 Khorana, 1922-2011

FIGURE 27-7 “Dictionary” of amino acid code words in mRNAs. The codons are written in the 5'—3' direction. The third base of each codon (in bold type) plays a lesser role in specifying an amino acid than the first two. The three termination codons are shaded in light red, the initiation codon AUG in green. All the amino acids except methionine and tryptophan have more than one codon. In most cases, codons that specify the same amino acid differ only at the third base. molecule begins and it is maintained as the synthetic machinery reads sequentially from one triplet to the next. If the initial reading frame is off by one or two bases, or if translation somehow skips a nucleotide in the mRNA, all the subsequent codons will be out of register; the result is usually a “missense” protein with a garbled amino acid sequence. Several codons serve special functions (Fig. 27-7). The initiation codon AUG is the most common signal for the beginning of a polypeptide in all cells, in addition to coding for Met residues in internal positions of polypeptides. The termination codons (UAA, UAG, and UGA), also called stop codons or nonsense codons, normally signal the end of polypeptide synthesis and do not code for any known amino acids. Some deviations from these rules are discussed in Box 27-1. As described in Section 27.2, initiation of protein synthesis in the cell is an elaborate process that relies on initiation codons and other signals in the mRNA. In retrospect, the experiments of Nirenberg,

Khorana, and others to identify codon function should not have worked in the absence of initiation codons. Serendipitously, experimental conditions caused the normal initiation requirements for protein synthesis to be relaxed. Diligence combined with chance to produce a breakthrough—a common occurrence in the history of biochemistry. In a random sequence of nucleotides, 1 in every 20 codons in each reading frame is, on average, a termination codon. In general, a reading frame without a termination codon among 50 or more codons is referred to as an open reading frame (ORF). Long open reading frames usually correspond to genes that encode proteins. In the analysis of sequence databases, sophisticated programs are used to search for open reading frames in order to find genes among the often huge background of nongenic DNA. An uninterrupted gene coding for a typical protein with a molecular weight of 60,000 would require an open reading frame with 500 or more codons. A striking feature of the genetic code is that an amino acid may be specified by more than one codon, so the code is described as degenerate. This does not suggest that the code is flawed: although an amino acid may have two or more codons, each codon specifies only one amino acid. The degeneracy of the code is not uniform. Whereas methionine and tryptophan have single codons, for example, three amino acids (Arg, Leu, Ser) have six codons, five amino acids have four, isoleucine has three, and nine amino acids have two (Table 27-3).

1108 Protein Metabolism In biochemistry, as in other disciplines, exceptions to general rules can be problematic for instructors and frustrating for students. At the same time, though, they teach us that life is complex and inspire us to search for more surprises. Understanding the exceptions can even reinforce the original rule in surprising ways. One would expect little room for variation in the genetic code. Even a single amino acid substitution can have profoundly deleterious effects on the structure of a protein. Nevertheless, variations in the code do occur in some organisms, and they are both interesting and instructive. The types of variation and their rarity provide powerful evidence for a common evolutionary origin of all living things. To alter the code, changes must occur in the gene(s) encoding one or more tRNAs, with the obvious target for alteration being the anticodon. Such a change would lead to the systematic insertion of an amino acid at a codon that, according to the standard code (see Fig. 27-7), does not specify that amino acid. The genetic code, in effect, is defined by two elements: (1) the anticodons on tRNAs (which determine where an amino acid is placed in a growing polypeptide) and (2) the specificity of the enzymes—the aminoacyl-tRNA synthetases—that charge the tRNAs, which determines the identity of the amino acid attached to a given tRNA. Most sudden changes in the code would have catastrophic effects on cellular proteins, so code alterations are more likely to persist where relatively few proteins would be affected—such as in small genomes encoding only a few proteins. The biological consequences of a code change could also be limited by restricting changes to the three termination codons, which do not generally occur within genes (see Box 27-4 for exceptions to this rule). This pattern is in fact observed. Of the very few variations in the genetic code that we know of, most occur in mitochondrial DNA (mtDNA), which encodes only 10 to 20 proteins. Mitochondria have their own tRNAs, so their code variations do not affect the much larger cellular genome. The most common changes in mitochondria involve termination codons. These changes affect termination in the products of only a subset of genes, and sometimes the effects are minor because the genes have multiple (redundant) termination codons. Vertebrate mtDNAs have genes that encode 13 proteins, 2 rRNAs, and 22 tRNAs (see Fig. 19-40a). The genetic code is nearly universal. With the

intriguing exception of a few minor variations in mitochondria, some bacteria, and some single-celled eukaryotes (Box 27-1), amino acid codons are identical in all species examined so far. Human beings, *E. coli*, tobacco plants, amphibians, and viruses share the same genetic code. Thus it would appear that all life-forms have a common evolutionary ancestor, whose genetic code has BOX 27-1 Exceptions That Prove the Rule: Natural Variations in the Genetic Code small number of codon reassignments, along with an unusual set of wobble rules (p. 1110), makes the 22 tRNAs sufficient to decode the protein genes, as opposed to the 32 tRNAs required for the standard code. In mitochondria, these changes can be viewed as a kind of genomic streamlining, as a smaller genome confers a replication advantage on the organelle. Four codon families (in which the amino acid is determined entirely by the first two nucleotides) are decoded by a single tRNA with a U residue in the first (or wobble) position in the anticodon. Either the U pairs somehow with any of the four possible bases in the third position of the codon or a “two out of three” mechanism is used—that is, no base pairing is needed at the third position. Other tRNAs recognize codons with either A or G in the third position, and yet others recognize U or C, so that virtually all the tRNAs recognize either two or four codons. In the standard code, only two amino acids are specified by single codons: methionine and tryptophan (see Table 27-3). If all mitochondrial tRNAs recognize two codons, we would expect additional Met and Trp codons in mitochondria. And we find that the single most common code variation is the normal termination codon UGA specifying tryptophan. The tRNA^{Trp} recognizes and inserts a Trp residue at either UGA or the normal Trp codon, UGG. The second most common variation is conversion of AUA from an Ile codon to a Met codon; the normal Met codon is AUG, and a single tRNA recognizes both codons. The known coding variations in mitochondria are summarized in Table 1. Turning to the much rarer changes in the codes for cellular (as distinct from mitochondrial) genomes, we find that the only known variation in a bacterium is again the use of UGA to encode Trp residues, occurring in the simplest free-living cell, *Mycoplasma capricolum*. Among eukaryotes, rare extramitochondrial coding changes occur in a few species of ciliated protists, in which both termination codons UAA and UAG can specify glutamine. There are also rare but interesting cases where stop codons have been adapted to encode amino acids

that are not among the standard 20, as detailed in Box 27-3. Changes in the code need not be absolute; a codon might not always encode the same amino acid. For example, in many bacteria—including *E. coli*—GUG (Val) is sometimes used as an initiation codon that specifies Met. This occurs only for those genes in been preserved throughout biological evolution. Even the variations reinforce this theme. Wobble Allows Some tRNAs to Recognize More than One Codon When several different codons specify one amino acid, the difference between them usually lies at the third

which the GUG is properly located relative to particular mRNA sequences that affect the initiation of translation (as discussed in Section 27.2). The most surprising alteration in the genetic code occurs in some fungal species of the genus *Candida*, as originally discovered for *Candida albicans*. *C. albicans* is an organism of high genomic complexity, yet its genetic code has undergone a dramatic change: the CUG codon, which normally encodes Leu, encodes Ser instead. The natural selection pressure for this change is completely unknown. Furthermore, the chemical nature of Ser and Leu are quite different. However, even this change can be understood based on the properties of a universal code. When several codons encode the same amino acid and utilize multiple tRNAs, not all of the codons are used with equal frequency. In a phenomenon called codon bias, some codons for a particular amino acid are used more frequently (sometimes much more frequently) than others. The tRNAs for the frequently used codons are often present at much higher concentrations than the tRNAs required for the rarely used codons. Code degeneracy leads to the presence of six codons for Leu. In bacteria, CUG is used often to encode Leu. However, in fungi in the genera that are very closely related to *Candida* but do not base position (at the 3' end). For example, alanine is coded by the triplets GCU, GCC, GCA, and GCG. The codons for most amino acids can be symbolized by XY or XY ϕ . The first two letters of each codon are the primary determinants of specificity, a feature that has some interesting consequences. Transfer RNAs base-pair with mRNA codons at a three-base sequence on the tRNA called the anticodon. In *Candida*, the coding change, the CUG codon is used quite rarely to encode Leu and is often entirely absent in highly expressed proteins. A change in the coding sense of

CUG would thus have a much smaller effect on fungal cell metabolism than might be anticipated if all codons were used equally. The coding change may have occurred by a gradual loss of CUG codons in genes and the tRNA that recognizes CUG as a Leu codon, followed by a capture event—a mutation in the anticodon of a tRNA** that allowed it to recognize CUG. Alternatively, there may have been an intermediate stage in which CUG was recognized as encoding both Leu and Ser, perhaps with contextual signals in the mRNAs that helped one tRNA or another to recognize specific CUG codons (see Box 27-3). Phylogenetic analysis indicates that the reassignment of CUG as a Ser codon occurred in *Candida* ancestors about 150 to 170 million years ago. These variations tell us that the code is not quite as universal as once believed, but that its flexibility is severely constrained. The variations are obviously derivatives of the normal code, and no example of a completely different code has been found. The limited scope of code variants strengthens the principle that all life on this planet evolved on the basis of a single (slightly flexible) genetic code. don. The first base of the codon in mRNA (read in the 5'—3' direction) pairs with the third base of the anticodon (Fig. 27-8a). If the anticodon triplet of a tRNA recognized only one codon triplet through WatsonCrick base pairing at all three positions, cells would have a different tRNA for each amino acid codon. This is not the case, however, because the anticodons in some tRNAs include the nucleotide inosinate (designated I),

 relationship of codon and anticodon. (a) Alignment of the two RNAs
 is antiparallel. The tRNA is shown in the traditional cloverleaf
 configuration. (b) Three different codon pairing relationships are
 possible when the tRNA anticodon contains inosinate, which
 contains the uncommon base hypoxanthine (see Fig. 8-5b).
 Inosinate can form hydrogen bonds with three different nucleotides
 (U, C, and A; Fig. 27-8b), although these pairings are much weaker
 than the hydrogen bonds of Watson-Crick base pairs G = C and
 A = U. In yeast, one tRNA^{arg} has the anticodon (5')ICG, which
 recognizes three arginine codons: (5')CGA, (5')CGU, and (5')CGC.
 The first two bases are identical (CG) and form strong Watson-Crick
 base pairs with the corresponding bases of the anticodon, but the
 third base (A, U, or C) forms rather weak hydrogen bonds with the I
 residue at the first position of the anticodon. Examination of these
 and other codon-anticodon pairings led Crick to conclude that the
 third base of most codons pairs rather loosely with the
 corresponding base of its anticodon; to use his picturesque word,
 the third base of such codons (and the first base of their
 corresponding anticodons) "wobbles." Crick proposed a set of four
 relationships called the wobble hypothesis: 1. The first two bases of
 an mRNA codon always form strong Watson-Crick base pairs with
 the corresponding bases of the tRNA anticodon and confer most of
 the coding specificity. 2. The first base of the anticodon (reading in
 the 5'—3' direction; this pairs with the third base of the codon)
 determines the number of codons recognized by the tRNA. When
 the first base of the anticodon is C or A, base pairing is specific and
 only one codon is recognized by that tRNA. When the first base is U
 or G, binding is less specific and two different codons may be read.
 When inosine (I) is the first (wobble) nucleotide of an anticodon,
 three different codons can be recognized—the maximum number
 for any tRNA. These relationships are summarized in Table 27-4. 3.
 When an amino acid is specified by several different codons, the
 codons that differ in either of the first two bases require different
 tRNAs. 4. A minimum of 32 tRNAs are required to translate all 61
 codons (31 to encode the amino acids and 1 for initiation). The
 wobble (or third) base of the codon contributes to specificity, but,

because it pairs only loosely with its corresponding base in the anticodon, it permits rapid dissociation of the tRNA from its codon during protein synthesis. If all three bases of a codon engaged in strong Watson-Crick pairing with the three bases of the anticodon, tRNAs would dissociate too slowly and this would limit the rate of protein synthesis. Codon-anticodon interactions balance the requirements for accuracy and speed. The Genetic Code Is Mutation-Resistant The genetic code plays an interesting role in safeguarding the genomic integrity of every living organism. Evolution did not produce a code in which codon assignments How the Wobble Base of the Anticodon Determines the Number of Codons a tRNA Can Recognize

1. One codon recognized: Anticodon (3')X-Y-C (5) (8) X-Y-A G5') Codon (5') X'-Y-G (3) 6) X-Y-U (3) 2. Two codons recognized: Anticodon (3) X-Y- U (5) (8) X-Y-G (5) Codon (5')X'-Y-@ 89 6) X-Y-§ (3) 3. Three codons recognized: Anticodon Corea io) Codon (5') x-y8 (3') Note: X and Y denote bases complementary to and capable of strong Watson-Crick base pairing with X' and Y', respectively. Wobble bases—in the 3' position of codons and 5' position of anticodons—are shaded in white.

appeared at random. Instead, the code is strikingly resistant to the deleterious effects of the most common kinds of mutations—missense mutations, in which a single new base pair replaces another. In the third, or wobble, position of the codon, single base substitutions produce a change in the encoded amino acid only about 25% of the time. Most such changes are thus silent mutations, where the nucleotide is different but the encoded amino acid remains the same. Due to the types of spontaneous DNA damage that affect genomes (see Chapter 8), the most frequent missense mutation is a transition mutation, where a purine is replaced by a purine or a pyrimidine by a pyrimidine (for example, G = C changed to A = T). All three codon positions have evolved so that there is some resistance to transition mutations. A mutation in the first position of the codon will usually result in an amino acid coding change, but the change often involves an amino acid with similar chemical properties. This is especially true for the hydrophobic amino acids that dominate the first column of the code shown in Figure 27-7. Consider the Val codon GUU. A change to AUU would substitute Ile for Val. A change to CUU would replace Val with Leu. The resulting changes in the structure and/or function of the protein encoded by that gene would often (but not always) be small. Computational studies have shown that genetic codes delineated at random are almost always less resistant to mutation than the existing code. The results indicate that the code underwent considerable streamlining prior to the appearance of LUCA, the ancestral cell. The genetic code tells us how protein sequence information is stored in nucleic acids and provides some clues about how that information is translated into protein.

Translational Frameshifting and RNA Editing Affect How the Code Is Read Once the reading frame has been set during protein synthesis, codons are translated without overlap or punctuation until the ribosomal complex encounters a termination codon. The other two possible reading frames usually contain no useful genetic information, but a few genes are structured so that ribosomes “hiccup” at a certain point in the translation of their mRNAs, changing the reading frame from that point on. This appears to be a mechanism either to allow two or more related but gag reading frame = = = Leu Gly Leu Arg Leu Thr

27.1 The Genetic Code 1111 distinct proteins to be produced from a single transcript or to regulate the synthesis of a

protein. One of the best-documented examples of translational frameshifting occurs during translation of the mRNA for the overlapping gag and pol genes of the Rous sarcoma virus (see Fig. 26-34). The reading frame for pol is offset to the left by one base pair (—1 reading frame) relative to the reading frame for gag (Fig. 27-9). The product of the pol gene (reverse transcriptase) is translated as a larger polyprotein, on the same mRNA that is used for the gag protein alone (see Fig. 26-33). The polyprotein, or gag-pol protein, is then trimmed to the mature reverse transcriptase by proteolytic digestion. Production of the polyprotein requires a translational frameshift in the overlap region to allow the ribosome to bypass the UAG termination codon at the end of the gag gene (shaded light red in Fig. 27-9). Frameshifts occur during about 5% of translations of this mRNA, and the gag-pol polyprotein (and ultimately reverse transcriptase) is synthesized at about one-twentieth the frequency of the gag protein, a level that suffices for efficient reproduction of the virus. In some retroviruses, another translational frameshift allows translation of an even larger polyprotein that includes the product of the env gene fused to the gag and pol gene products (see Fig. 26-33). A similar mechanism produces both the 7 and γ subunits of E. coli DNA polymerase III from a single dnaX gene transcript (see Table 25-2). Some mRNAs are edited before translation. RNA editing can involve the addition, deletion, or alteration of nucleotides in the RNA in a manner that affects the meaning of the transcript when it is translated. Addition or deletion of nucleotides has been most commonly observed in RNAs originating from the mitochondrial and chloroplast genomes of eukaryotes. The reactions require a special class of RNA molecules encoded by these same organelles, with sequences complementary to the edited mRNAs. These guide RNAs (gRNAs; Fig. 27-10) act as templates for the editing process. The initial transcripts of the genes that encode cytochrome oxidase subunit II in some protist mitochondria provide an example of editing by insertion. These transcripts do not correspond precisely to the sequence needed at the carboxyl terminus of the protein product. A posttranscriptional editing process inserts four U residues that shift the translational reading frame

Figure 27-10 shows the added U residues in the small part of the transcript that is affected by editing. Note that the base pairing between the initial transcript and the guide RNA involves a number of G=U base pairs (blue dots), which are common in RNA molecules. RNA editing by alteration of nucleotides most commonly involves the enzymatic deamination of adenosine or cytidine residues, forming inosine or uridine, respectively (Fig. 27-11), although other base changes have been described. Inosine is interpreted as a G residue during translation. The adenosine deamination reactions are carried out by adenosine deaminases that act on RNA (ADARs). The cytidine deaminations are carried out by the apoB mRNA editing catalytic peptide (APOBEC) family of enzymes, which includes the related activation-induced deaminase (AID) enzymes. Both groups of deaminase enzymes have a homologous zinc-coordinating catalytic domain. A well-studied example of RNA editing by deamination occurs in the gene for the apolipoprotein B component of low-density lipoprotein in vertebrates. One form of apolipoprotein B, apoB-100 (M, 513,000), is synthesized in the liver; a second form, apoB-48 (M, 250,000), is synthesized in the intestine. Both are encoded by an mRNA produced from the gene for apoB-100. An APOBEC cytidine deaminase found only in the intestine binds to the mRNA at the codon for amino acid residue 2,153 (CAA = Gln) and converts the C to a U to create the termination codon UAA. FIGURE 27-12 RNA editing of the transcript of the gene for the apoB100 component of LDL. Deamination, which occurs only in the intestine, the intestine from this modified mRNA is simply an abbreviated form (corresponding to the amino-terminal half) of apoB-100 (Fig. 27-12). This reaction permits tissue-specific synthesis of two different proteins from one gene. The ADAR-promoted A-to-I editing is particularly common in transcripts derived from the genes of primates. Perhaps 90% or more of the editing occurs in Alu elements, a subset of the eukaryotic transposons called short interspersed elements (SINEs), that are particularly common in mammalian genomes. There are over a million of the 300 bp Alu elements in human DNA, making up about 10% of the genome. These are concentrated near protein-encoding genes, often appearing in introns and untranslated regions at the 3' and 5' ends of transcripts. When it is first synthesized (prior to processing), the average human mRNA includes 10 to 20 Alu elements. The ADAR enzymes bind to and promote A-to-I editing only in duplex regions of RNA. The abundant Alu elements offer many opportunities for intramolecular base pairing within the transcripts, providing the duplex targets required by the ADARs. Some of the editing affects the coding sequences of genes. Defects in ADAR function have been associated with a variety of human neurological conditions, including amyotrophic lateral sclerosis (ALS), epilepsy, and major depression. The genomes of all vertebrates are replete with SINEs, but many different types of SINES are present in most of these organisms. The Alu elements predominate only in the primates. Careful screening of genes and transcripts indicates that A-to-I editing is 30 to 40 times more prevalent in humans than in mice, largely due to the presence of many Alu elements. Large-scale A-to-I editing and an increased level of alternative splicing (see Fig. 26-21) are two features that set primate genomes apart from those of other mammals. It is not yet clear whether these reactions are incidental or whether they played

key roles in the evolution of primates and, ultimately, humans.

SUMMARY 27.1 The Genetic Code > The particular amino acid sequence of a protein is constructed through the translation of information encoded in mRNA. This process is carried out by ribosomes. > Amino acids are specified by mRNA codons consisting of nucleotide triplets. Translation converts a specific cytidine to uridine, changing a Gln codon to a stop codon and producing a truncated protein. requires adaptor molecules, the tRNAs, that recognize codons and insert amino acids into their appropriate sequential positions in the polypeptide. > The base sequences of the codons were deduced from experiments using synthetic mRNAs of known composition and sequence. > The codon AUG signals initiation of translation. The triplets UAA, UAG, and UGA are signals for termination. > The genetic code is degenerate: it has multiple codons for almost every amino acid. > The standard genetic code is universal in all species, with some minor deviations in mitochondria and a few single-celled organisms. The deviations occur in a pattern that reinforces the concept of a universal code. > The third position in each codon is much less specific than the first and second and is said to wobble. > The genetic code is resistant to the effects of missense mutations. > Translational frameshifting and RNA editing affect how the genetic code is read during translation.

27.2 Protein Synthesis As we have seen for DNA and RNA (Chapters 25 and 26), the synthesis of polymeric biomolecules can be considered in terms of initiation, elongation, and termination stages. These fundamental processes are typically bracketed by two additional stages: activation of precursors before synthesis and postsynthetic processing of the completed polymer. Protein synthesis follows the same pattern. The activation of amino acids before their incorporation into polypeptides and the posttranslational processing of the completed polypeptide play particularly important roles in ensuring both the fidelity of synthesis and the proper function of the protein product. The process is outlined in Figure 27-13. The cellular components involved in the five stages of protein synthesis in *E. coli* and other bacteria are listed in Table 27-5; the requirements in eukaryotic cells are quite similar, although the components are in some cases more numerous. An initial overview of the stages of protein synthesis provides a useful outline for the discussion that follows.

1114 Protein Metabolism (2) Initiation: the mRNA and the aminoacylated tRNA bind to the small ribosomal subunit. The large subunit then binds as well. Aminoacyl-tRNA (1) Activation of amino acids: the tRNA is aminoacylated N j A © Start Stop mRNA (4) Termination: translation stops when a stop codon is encountered. The mRNA and protein dissociate and the ribosomal subunits are recycled. © Protein folding & FIGURE 27-13 An overview of the five stages of protein synthesis. @ The tRNAs are aminoacylated. @ Translation initiation occurs when an mRNA and an aminoacylated tRNA are bound to the ribosome. © In elongation, the ribosome moves along the mRNA, matching tRNAs to each codon and catalyzing peptide bond formation. @ Translation is Protein Biosynthesis Takes Place in Five Stages Stage 1: Activation of Amino Acids For the synthesis of a polypeptide with a defined sequence, two fundamental chemical requirements must be met: (1) the carboxyl group of each amino acid must be activated to facilitate formation of a peptide bond, and (2) a link must be established between each new amino acid and the information in the mRNA that encodes it. Both these requirements are met by attaching the amino acid to a tRNA in the first stage of protein synthesis. Attaching the right amino acid to the right tRNA is critical. This reaction takes place in the cytosol, not on the ribosome. Each of the 20 amino acids is covalently attached to a specific tRNA at the expense of ATP energy, using Mg^{2+} -dependent activating enzymes known as aminoacyl-tRNA synthetases. When attached to their amino acid (aminoacylated) the tRNAs are said to be “charged.” Stage 2: Initiation The mRNA bearing the code for the polypeptide to be synthesized binds to the smaller of two ribosomal subunits and to the initiating aminoacyl-tRNA. The large ribosomal subunit then binds to form an initiation complex. The initiating aminoacyl-tRNA Large subunit (3) Elongation: successive cycles of aminoacyl-tRNA binding and peptide bond formation occur until ribosome reaches a stop codon. terminated at a stop codon, and the ribosomal subunits are released and recycled for another round of protein synthesis. @ Following synthesis, the protein must fold into its active conformation and ribosome components are recycled. base-pairs with the mRNA codon AUG that signals the beginning of the polypeptide. This process, which requires GTP, is promoted by cytosolic proteins called initiation factors. Stage 3: Elongation The

nascent polypeptide is lengthened by covalent attachment of successive amino acid units, each carried to the ribosome and correctly positioned by its tRNA, which base-pairs to its corresponding codon in the mRNA. Elongation requires cytosolic proteins known as elongation factors. The binding of each incoming aminoacyl-tRNA and the movement of the ribosome along the mRNA are facilitated by the hydrolysis of GTP as each residue is added to the growing polypeptide. Stage 4: Termination and Ribosome Recycling Completion of the polypeptide chain is signaled by a termination codon in the mRNA. The new polypeptide is released from the ribosome, aided by proteins called release factors, and the ribosome is recycled for another round of synthesis. Stage 5: Folding and Posttranslational Processing In order to achieve its biologically active form, the new polypeptide must fold into its proper three-dimensional conformation.

Before looking at these five stages in detail, we must examine two key components in protein biosynthesis: the ribosome and tRNAs. The Ribosome Is a Complex Supramolecular Machine Each *E. coli* cell contains 15,000 or more ribosomes, which comprise nearly a quarter of the dry weight of the cell. Bacterial ribosomes contain about 65% rRNA and 35% protein; they have a diameter of about 18 nm and are composed of two unequal subunits with sedimentation coefficients of 30S and 50S and a combined sedimentation coefficient of 70S. Both subunits contain dozens of ribosomal proteins and at least one large rRNA (Table 27-6). Following Zamecnik's discovery that ribosomes are the complexes responsible for protein synthesis, and following elucidation of the genetic code, the study of ribosomes accelerated. In the late 1960s Masayasu Nomura and colleagues demonstrated that both ribosomal subunits can be broken down into their RNA and protein components, then reconstituted in Masayasu Nomura, *vitro*. Under appropriate experimental conditions, the RNA and protein spontaneously reassemble to form 30S or 50S subunits

nearly identical in structure and activity to native subunits. This breakthrough fueled decades of research into the function and structure of ribosomal RNAs and proteins. At the same time, increasingly sophisticated structural methods revealed more and more details about ribosome structure.

1116 Protein Metabolism | TABLE 27-6 | (AE RNA and Protein Components of the E. coli Ribosome Number of Total number Protein Number and Subunit different proteins of proteins designations type of rRNAs 30S All 21 \$1-S21 1 (16S rRNA) 50S 23 36 L1-L36* 2 (5S and 23S rRNAs) *The L1 to L36 protein designations do not correspond to 36 different proteins. The protein originally designated L? is in fact a modified form of L12, and L8 is a complex of three other proteins. Also, L26 proved to be the same protein as 520 (and not part of the 50S subunit). This gives 33 different proteins in the large subunit. There are four copies of the L7/L12 protein, with the three extra copies bringing the total protein count to 36. The dawn of a new millennium brought with it the elucidation of the first high-resolution structures of bacterial ribosomal subunits by Thomas Steitz, Ada Yonath, Venki Ramakrishnan, Harry Noller, and others. This work yielded a wealth of surprises (Fig. 27-14a). First, a traditional focus on the protein components of ribosomes was shifted. The ribosomal subunits are huge RNA molecules. In the 50S subunit, the 5S and 23S rRNAs form the structural core. The proteins are secondary Venkatraman Ramakrishnan Thomas A. Steitz FIGURE 27-14 The structure of ribosomes. Our understanding of ribosome structure has been greatly enhanced by multiple high-resolution images of the ribosomes from bacteria and yeast. (a) The bacterial ribosome (derived from PDB ID 2OW8 and PDB ID 1VSA). The 50S and 30S Ada E. Yonath elements in the complex, decorating the surface. Second and most important, there is no protein within 18 Å of the active site for peptide bond formation. The high-resolution structure thus confirms what Harry Noller had predicted much earlier: the ribosome is a ribozyme. In addition to the insight that the detailed structures of the ribosome and its subunits provide into the mechanism of protein synthesis (as elaborated below), they have stimulated a new look at the evolution of life (Box 27-2). The ribosomes of eukaryotic cells have also yielded to structural analysis (Fig. 27-14b). The bacterial ribosome is complex, with a combined molecular weight of ~2.7 million. The two irregularly shaped ribosomal subunits fit together to form a cleft through which the mRNA passes as the ribosome moves along it during translation (Fig. 27—14a). The 57 proteins in bacterial ribosomes vary enormously in size and structure. Molecular weights range from

subunits come together to form the 70S ribosome. A cleft between them is where protein synthesis occurs. (b) The yeast ribosome has a similar structure with somewhat increased complexity (derived from PDB ID 3058 and PDB ID 302Z).

(b)

BOX 27-2 Extant ribozymes generally promote one of two types of reactions: hydrolytic cleavage of phosphodiester bonds or phosphoryl transfers (Chapter 26). In both cases, the substrates of the reactions are also RNA molecules. The ribosomal RNAs provide an important expansion of the catalytic range of known ribozymes. Coupled to the laboratory exploration of potential RNA catalytic function (see Box 26-3), the idea of an RNA world as a precursor to current life-forms becomes increasingly attractive. A viable RNA world would require an RNA capable of self-replication, a primitive metabolism to generate the needed ribonucleotide precursors, and a cell boundary to aid in concentrating the precursors and sequestering them from the environment. The requirements for catalysis of reactions involving a growing range of metabolites and macromolecules could have led to larger and more complex RNA catalysts. The many negatively charged phosphoryl groups in the RNA backbone limit the stability of very large RNA molecules. In an RNA world, divalent cations or other positively charged groups could be incorporated into the structures to augment stability. Certain peptides could stabilize large RNA molecules. For example, many ribosomal proteins in modern eukaryotic cells have long extensions, lacking a regular secondary structure, that snake into the rRNAs and help stabilize them (Fig. 1). Ribozyme-catalyzed synthesis of peptides could thus initially have evolved as part of a general solution to the structural maintenance of large RNA molecules. The synthesis of peptides may have helped stabilize large ribozymes, but this advance also marked the beginning of the end for the RNA world. Once peptide synthesis was possible, the greater catalytic potential of proteins would have set in motion an irreversible transition to a proteindominated metabolic system. Most enzymatic processes, then, were eventually surrendered to the proteins—but not all. In every organism, the critical task of synthesizing the proteins about 6,000 to 75,000. Most of the proteins have globular domains arranged on the ribosome surface. Some also have snakelike extensions that protrude into the rRNA core of the ribosome, stabilizing its structure. The functions of some of these proteins have not yet been elucidated in detail, although a structural role seems evident for many of them. The sequences of the rRNAs of many organisms are now known. Each of the three single-stranded rRNAs of *E. coli* has a specific three-dimensional

conformation featuring extensive intrachain base pairing. The folding patterns of the rRNAs are highly conserved in all organisms, particularly the regions implicated in key functions. From an RNA World to a Protein World remains, even now, a ribozyme-catalyzed process. There appears to be only one good arrangement (or just a very few) of nucleotide residues in a ribozyme active site that can catalyze peptide synthesis. The rRNA residues that seem to be involved in the peptidyl transferase activity of ribosomes are highly conserved in the large-subunit rRNAs of all species. Using in vitro evolution (SELEX; see Box 26-3), investigators have isolated artificial ribozymes that promote peptide synthesis. Intriguingly, most of them include the ribonucleotide octet (5')AUAACAGG(3'), a highly conserved sequence found at the peptidyl transferase active site in the ribosomes of all cells. There may be just one optimal solution to the overall chemical problem of ribozyme-catalyzed synthesis of proteins of defined sequence. Evolution found this solution once, and no life-form has notably improved on it.

FIGURE 1 The 50S subunit of a bacterial ribosome (PDB ID 1Q7Y). The protein backbones are shown as blue wormlike structures; the rRNA components are transparent. The unstructured extensions of many of the ribosomal proteins snake into the rRNA structures, helping to stabilize them. Bound puromycin, in red, marks the rRNA active site for peptidyl transferase reactions (Fig. 27-15). The predicted secondary structure of the rRNAs has largely been confirmed by structural analysis but fails to convey the extensive network of tertiary interactions apparent in the complete structure. The ribosomes of eukaryotic cells (other than mitochondrial and chloroplast ribosomes) are larger and more complex than bacterial ribosomes (Fig. 27-16; compare Fig. 27-14b), with a diameter of about 23 nm and a sedimentation coefficient of about 80S. They also have two subunits, which vary in size among species but on average are 60S and 40S. Altogether, eukaryotic ribosomes contain more than 80 different proteins. The ribosomes of mitochondria and chloroplasts are somewhat smaller

BOX 27-2 From an RNA World to a Protein World

Extant ribozymes generally promote one of two types of reactions: hydrolytic cleavage of phosphodiester bonds or phosphoryl transfers (Chapter 26). In both cases, the substrates of the reactions are also RNA molecules. The ribosomal RNAs provide an important expansion of the catalytic range of known ribozymes. Coupled to the laboratory exploration of potential RNA catalytic function (see Box 26-3), the idea of an RNA world as a precursor to current life-forms becomes increasingly attractive.

A viable RNA world would require an RNA capable of self-replication, a primitive metabolism to generate the needed ribonucleotide precursors, and a cell boundary to aid in concentrating the precursors and sequestering them from the environment. The requirements for catalysis of reactions involving a growing range of metabolites and macromolecules could have led to larger and more complex RNA catalysts. The many negatively charged phosphoryl groups in the RNA backbone limit the stability of very large RNA molecules. In an RNA world, divalent cations or other positively charged groups could be incorporated into the structures to augment stability.

Certain peptides could stabilize large RNA molecules. For example, many ribosomal proteins in modern eukaryotic cells have long extensions, lacking a regular secondary structure, that snake into the rRNAs and help stabilize them (Fig. 1). Ribozyme-catalyzed synthesis of peptides could thus initially have evolved as part of a general solution to the structural maintenance of large RNA molecules. The synthesis of peptides may have helped stabilize large ribozymes, but this advance also marked the beginning of the end for the RNA world. Once peptide synthesis was possible, the greater catalytic potential of proteins would have set in motion an irreversible transition to a protein-dominated metabolic system.

Most enzymatic processes, then, were eventually surrendered to the proteins—but not all. In every organism, the critical task of synthesizing the proteins

remains, even now, a ribozyme-catalyzed process. There appears to be only one good arrangement (or just a very few) of nucleotide residues in a ribozyme active site that can catalyze peptide synthesis. The rRNA residues that seem to be involved in the peptidyl transferase activity of ribosomes are highly conserved in the large-subunit rRNAs of all species. Using *in vitro* evolution (SELEX; see Box 26-3), investigators have isolated artificial ribozymes that promote peptide synthesis. Intriguingly, most of them include the ribonucleotide octet (5')AUAACAGG(3'), a highly conserved sequence found at the peptidyl transferase active site in the ribosomes of all cells. There may be just one optimal solution to the overall chemical problem of ribozyme-catalyzed synthesis of proteins of defined sequence. Evolution found this solution once, and no life-form has notably improved on it.

FIGURE 27-16 Summary of the composition and mass of ribosomes in bacteria and eukaryotes. Ribosomal subunits are identified by their S (Svedberg unit) values, sedimentation coefficients that refer to their rate of sedimentation in a centrifuge. The S values are not additive when subunits are combined, because S values are approximately proportional to the % power of molecular weight and are also slightly affected by shape. and simpler than bacterial ribosomes. Nevertheless, ribosomal structure and function are strikingly similar in all organisms and organelles.

Transfer RNAs Have Characteristic Structural Features To understand how tRNAs can serve as adaptors in translating the language of nucleic acids into the language of proteins, we must first examine their structure in more detail. Transfer RNAs are relatively small and consist of a single strand of RNA folded into a precise three-dimensional structure (see Fig. 8-25a). The tRNAs in bacteria and in the cytosol of eukaryotes have between 73 and 93 nucleotide residues, corresponding to molecular weights of 24,000 to 31,000. Mitochondria and chloroplasts contain distinctive, somewhat smaller tRNAs. Cells have at least one kind of tRNA for each amino acid; at least 32 tRNAs are required to recognize all the amino acid codons (some recognize more than one codon), but some cells use more than 32. Yeast alanine tRNA (tRNA^{ala}) was the first nucleic acid to be completely sequenced, by Robert Holley in 1965. It contains 76 nucleotide residues, 10 of which have modified bases. Comparisons of tRNAs from various species have revealed many common. structural features (Fig. 27-17). Eight or more of the nucleotide residues have modified bases and sugars, many of which are methylated derivatives of the principal bases. Most tRNAs have

a guanylate (pG) residue at the 5' end, and all have the trinucleotide sequence CCA(3') at the 3' end. When drawn in two dimensions, the hydrogen-bonding pattern of all tRNAs forms a cloverleaf structure with four arms; the longer tRNAs have a short fifth arm, or extra arm. In three dimensions, a tRNA has the form of a twisted L (Fig. 27-18). Two of the arms of a tRNA are critical for its adaptor function. The amino acid arm can carry a specific amino acid esterified by its carboxyl group to the 2' or 3'-hydroxyl group of the A residue at the 3' end of the tRNA. The anticodon arm contains the anticodon. The other major arms are the D arm, which contains the unusual nucleotide dihydrouridine (D), and the TyC arm, which contains ribothymidine (T), not usually present in RNAs, and pseudouridine (y), which has an unusual carbon-carbon bond between the base and ribose (see Fig. 26-22). The D and TwC arms contribute important interactions for the overall folding of tRNA molecules, and the TwC arm interacts with the large subunit rRNA. Having looked at the structures of ribosomes and tRNAs, we now consider in detail the five stages of protein synthesis. Robert W. Holley, 1922-1993

Amino acid Contains two or three Variable in size, D residues not present in at different all tRNAs positions Anticodon

Figure 27-17 General cloverleaf secondary structure of tRNAs. The large dots on the backbone represent nucleotide residues; the blue lines represent base pairs. Characteristic and/or invariant residues common to all tRNAs are shaded in light red. Transfer RNAs vary in length from 73 to 93 nucleotides. Extra nucleotides occur in the extra arm or in the D arm. At the end of the anticodon arm is the anticodon loop, which always contains seven unpaired nucleotides. The D arm contains two or three D (5,6-dihydrouridine) residues, depending on the tRNA. In some tRNAs, the D arm has only three hydrogen-bonded base pairs. Symbols are: Pu, purine nucleotide; Py, pyrimidine nucleotide; w, pseudouridylate; G*, either guanylate or 2'-O-methylguanylate. 27.2 Protein Synthesis 1119 Stage 1: Aminoacyl-tRNA Synthetases Attach the Correct Amino Acids to Their tRNAs During the first stage of protein synthesis, taking place in the cytosol, aminoacyl-tRNA synthetases esterify the 20 amino acids to their corresponding tRNAs. Each enzyme is specific for one amino acid and one or more corresponding tRNAs. Most organisms have one aminoacyl-tRNA synthetase for each amino acid. For amino acids with two or more corresponding tRNAs, the same enzyme usually aminoacylates all of them. The structures of all the aminoacyl-tRNA synthetases of *E. coli* have been determined. Researchers have divided them into two classes (Table 27-7) based on substantial differences in primary and tertiary structure and in reaction mechanism (Fig. 27-19); these two classes are the same in all organisms. There is no LUYA

The Two Classes of Aminoacyl-tRNA Synthetases Class | Class II Arg Leu Ala Lys Cys Met Asn Phe Gln Trp Asp Pro Glu Tyr Gly Ser Thr Val His Thr Note: Here, Arg represents arginyl-tRNA synthetase, and so forth. The classification applies to all organisms for which tRNA synthetases have been analyzed and is based on protein structural distinctions and on the mechanistic distinction outlined in Figure 27-19. space-filling model, with the same color coding (PDB ID 4TRA). The CCA sequence at the 3' end (purple) is the attachment point for the amino acid.

1120 Protein Metabolism MECHANISM FIGURE 27-19

Aminoacylation of tRNA by aminoacyl-tRNA synthetases. $O=P(O)(OH)CH_2-$ is formation of an aminoacyl adenylate, which remains bound to the active site. In Adenine the second step the aminoacyl group is transferred to the amino acid ATP, forming 5'-aminoacyl AMP; group is transferred initially to the 2'-hydroxyl group of the 3'-terminal A residue, then to the 3'-hydroxyl group by a transesterification reaction. For class I enzymes, the aminoacyl group is transferred directly to the 3'-hydroxyl group of the terminal adenylate. In Adenine 5'-Aminoacyl adenylate (aminoacyl-AMP) class I aminoacyl-tRNA synthetases 3' end of tRNA Adenine Adenine $P=O$ Adenosine $O=P(O)(OH)CH_2-$ Adenosine CH_2- Aminoacyl-AMP | Aminoacyl-AMP is transferred to the AMP 2' $-OH$ of the 3'-terminal A residue AMP 3' $-OH$ of the 3'-terminal A residue of tRNA, of tRNA, releasing AMP. generating the aminoacyl-tRNA product. Adenine Adenine $H-OH$ $O=O$ 70 (H_2O) transesterification $\circ$ DS $@$ ES a O Transesterification moves O aminoacyl group to 3' $-OH$ of the same tRNA residue, generating the aminoacyl-tRNA product. Aminoacyl-tRNA

evidence that the two classes share a common ancestor, and the biological, chemical, or evolutionary reasons for two enzyme classes for essentially identical processes remain obscure. The reaction catalyzed by an aminoacyl-tRNA synthetase is $\text{Amino acid} + \text{tRNA} + \text{ATP} \Rightarrow \text{aminoacyl-tRNA} + \text{AMP} + \text{PP}$; This reaction occurs in two steps in the enzyme's active site. In step ① (Fig. 27-19) an enzyme-bound intermediate, aminoacyl adenylate (aminoacyl-AMP), is formed. In the second step the aminoacyl group is transferred from enzyme-bound aminoacyl-AMP to its corresponding specific tRNA. The course of this second step depends on the class to which the enzyme belongs, as shown by pathways @ and @ in Figure 27-19. The resulting ester linkage between the amino acid and the tRNA (Fig. 27-20) has a highly negative standard free energy of hydrolysis ($\Delta G'^{\circ} = -29 \text{ kJ/mol}$). The pyrophosphate formed in the activation reaction undergoes hydrolysis to phosphate by inorganic pyrophosphatase. Thus two high-energy phosphate bonds are ultimately expended for each amino acid molecule activated, rendering the overall reaction for amino acid activation essentially irreversible: $\text{Amino acid} + \text{tRNA} + \text{ATP} \Rightarrow \text{aminoacyl-tRNA} + \text{AMP} + 2\text{P}$; $\Delta G'^{\circ} = -29 \text{ kJ/mol}$

Proofreading by Aminoacyl-tRNA Synthetases The aminoacylation of tRNA accomplishes two ends: (1) it activates an amino acid for peptide bond formation and (2) it 3' end of tRNA Adenine H l o j C —R CH, “tn, ° Aminoacyl “O—P=O oe ò arm arm Anticodon arm

27.2 Protein Synthesis 1121

ensures appropriate placement of the amino acid in a growing polypeptide. The identity of the amino acid attached to a tRNA is not checked on the ribosome, so attachment of the correct amino acid to the tRNA is essential to the fidelity of protein synthesis. As you will recall from Chapter 6, enzyme specificity is limited by the binding energy available from enzyme-substrate interactions. Discrimination between two similar amino acid substrates has been studied in detail in the case of Ile-tRNA synthetase, which distinguishes between valine and isoleucine, amino acids that differ by only a single methylene group (—CH₂—):

COO COO + | + ae la
Gam a ie CH; -o CH₃ CH; CH, CH; Valine Isoleucine Ile-tRNA

synthetase favors activation of isoleucine (to form Ile-AMP) over valine by a factor of 200—as we would expect, given the amount by which a methylene group (in Ile) could enhance substrate binding. Yet valine is erroneously incorporated into proteins in positions normally occupied by an Ile residue at a frequency of only about 1 in 3,000. How is this greater than 10-fold increase in accuracy brought about? Ile-tRNA synthetase, like some other aminoacyl-tRNA synthetases, has a proofreading function. Recall a general principle from the discussion of proofreading by DNA polymerases (see Fig. 25-7): if available binding interactions do not provide sufficient discrimination between two substrates, the necessary specificity can be achieved by substrate-specific binding in two successive steps. The effect of forcing the system through two successive filters is multiplicative. In the case of Ile-tRNA synthetase, the first filter is the initial binding of the amino acid to the enzyme and its activation to aminoacyl-AMP. The second is the binding of any incorrect aminoacyl-AMP products to a separate active site on the enzyme; a substrate that binds in this second active site is hydrolyzed. The R group of valine is slightly smaller than that of isoleucine, so Val-AMP fits the hydrolytic (proofreading) site of the Ile-tRNA synthetase but Ile-AMP does not. Thus Val-AMP is hydrolyzed to valine and AMP in the proofreading active site, and tRNA bound to the synthetase does not become aminoacylated to the wrong amino acid. In addition to proofreading after formation of the aminoacyl-AMP intermediate, most aminoacyl-tRNA synthetases can hydrolyze the ester linkage between amino acids and tRNAs in the aminoacyl-tRNAs. This hydrolysis is greatly accelerated for incorrectly charged tRNAs, providing yet a third filter to enhance the fidelity of the

1122 Protein Metabolism overall process. The few aminoacyl-tRNA synthetases that activate amino acids with no close structural relatives (Cys-tRNA synthetase, for example) demonstrate little or no proofreading activity; in these cases, the active site for aminoacylation can sufficiently discriminate between the proper substrate and any incorrect amino acid. The overall error rate of protein synthesis (~ 1 mistake per 10^4 amino acids incorporated) is not nearly as low as that of DNA replication. Because flaws in a protein are eliminated when the protein is degraded and are not passed on to future generations, they have less biological significance. The degree of fidelity in protein synthesis is sufficient to ensure that most proteins contain no mistakes and that the large amount of energy required to synthesize a protein is rarely wasted. One defective protein molecule is usually unimportant when many correct copies of the same protein are present. Interaction between an Aminoacyl-tRNA Synthetase and a tRNA: A "Second Genetic Code" An individual aminoacyl-tRNA synthetase must be specific not only for a single amino acid but for certain tRNAs as well. Discriminating among dozens of tRNAs is just as important for the overall fidelity of protein biosynthesis as is distinguishing among amino acids. The interaction between aminoacyl-tRNA synthetases and tRNAs has been referred to as the 3rd Amino acid arm Extra arm Anticodon arm 5' to 3' (a) Anticodon

FIGURE 27-21 Nucleotide positions in tRNAs that are recognized by aminoacyl-tRNA synthetases. (a) Some positions (purple dots) are the same in all tRNAs and therefore cannot be used to discriminate one from another. Other positions are known recognition points for one (orange) or more (blue) aminoacyl-tRNA synthetases. Structural features other than the "second genetic code," reflecting its critical role in maintaining the accuracy of protein synthesis. The "coding" rules appear to be more complex than those in the "first" code. Figure 27-21 summarizes what we know about the nucleotides involved in recognition by some aminoacyl-tRNA synthetases. Some nucleotides are conserved in all tRNAs and therefore cannot be used for discrimination. By observing changes in nucleotides that alter substrate specificity, researchers have identified nucleotide positions that are involved in discrimination by the aminoacyl-tRNA synthetases. These nucleotide positions seem to be concentrated in the amino acid arm and the anticodon arm, including the

nucleotides of the anticodon itself, but are also located in other parts of the tRNA molecule. Determination of the crystal structures of aminoacyl-tRNA synthetases complexed with their cognate tRNAs and ATP has added a great deal to our understanding of these interactions (Fig. 27-22). Ten or more specific nucleotides may be involved in recognition of a tRNA by its specific aminoacyl-tRNA synthetase. But in a few cases the recognition mechanism is quite simple. Across a range of organisms from bacteria to humans, the primary determinant of tRNA recognition by the Ala-tRNA synthetases is a single G = U base pair in the Amino acid arm. Darn Anticodon (b) than sequence are important for recognition by some of the synthetases. (b) (PDB ID 1EHZ) The same structural features are shown in three dimensions, with the orange and blue residues again representing positions recognized by one or more aminoacyl-tRNA synthetases, respectively.

(a) FIGURE 27-22 Aminoacyl-tRNA synthetases. Both synthetases are complexed with their cognate tRNAs (green). Bound ATP (red) pinpoints the active site near the end of the aminoacyl arm. (a) Gln-tRNA synthetase amino acid arm of tRNA^{Asp} (Fig. 27-23a). A short synthetic RNA with as few as 7 bp arranged in a simple hairpin minihelix is efficiently aminoacylated by the Ala-tRNA synthetase, as long as the RNA contains the critical G = U (Fig. 27-23b). This relatively simple alanine system may be an evolutionary relic of a period when RNA oligonucleotides, ancestors to tRNA, were aminoacylated in a primitive system for protein synthesis. (a) (b) 6 ~\ Deleted 73 "nucleotides 27.2 Protein Synthesis 1123 (b) from *E. coli*, a typical monomeric class I synthetase (PDB ID 1QRT). (b) Asp-tRNA synthetase from yeast, a typical dimeric class II synthetase (PDB ID 1ASZ). The interaction of aminoacyl-tRNA synthetases and their cognate tRNAs is critical to accurate reading of the genetic code. Any expansion of the code to include new amino acids would necessarily require a new aminoacyl-tRNA synthetase:tRNA pair. A limited expansion of the genetic code has been observed in nature; a more extensive expansion has been accomplished in the laboratory (Box 27-3).

FIGURE 27-23 Structural elements of tRNA^{Ala} that are required for recognition by Ala-tRNA synthetase. (a) The tRNA^{Ala} structural elements recognized by the Ala-tRNA synthetase are unusually simple. A single G = U base pair (light red) is the only element needed for specific binding and aminoacylation. (b) A short synthetic RNA minihelix, with the critical G = U base pair but lacking most of the remaining tRNA structure. This is aminoacylated specifically with alanine almost as efficiently as the complete tRNA^{Ala}.

1124 Protein Metabolism As we have seen, the 20 amino acids commonly found in proteins offer only limited chemical functionality. Living systems generally overcome these limitations by using enzymatic cofactors or by modifying particular amino acids after they have been incorporated into proteins. In principle, expansion of the genetic code to introduce new amino acids into proteins offers another route to new functionality, but it is a very difficult route to exploit. Such a change might just as easily result in the inactivation of thousands of cellular proteins. Expanding the genetic code to include a new amino acid requires several cellular changes. A new aminoacyl-tRNA synthetase must generally be present, along with a cognate tRNA. Both of these components must be highly specific, interacting only with each other and the new amino acid. Significant concentrations of the new amino acid must be present in the cell, which may entail the evolution of new metabolic pathways. As outlined in Box 27-1, the anticodon on the tRNA would most likely pair with a codon that normally specifies termination. Making all of this work in a living cell seems unlikely, but it has happened both in nature and in the laboratory. There are actually 22 rather than 20 amino acids specified by the known genetic code. The two extra ones are selenocysteine and pyrrolysine, each found in only very few proteins but both offering a glimpse into the intricacies of code evolution.

coo- cooTE H₂N—CH dn, CH, Solt CH, Selenocysteine Ott, CH, WH CH, na y=

Pyrrolysine A few proteins in all cells (such as formate dehydrogenase in bacteria and glutathione peroxidase in mammals) require selenocysteine for their activity. In *E. coli* selenocysteine is introduced into the enzyme formate dehydrogenase during translation, in response to an in-frame UGA codon. A special type of Ser-tRNA, present at lower levels than other Ser-tRNAs, recognizes UGA and no other codons. This tRNA is charged with serine by the normal serine aminoacyl-tRNA BOX 27-3 Natural and Unnatural Expansion of the Genetic Code synthetase, and the serine is enzymatically converted to selenocysteine by a separate enzyme before its use at the ribosome. The charged tRNA does not recognize just any UGA codon; some contextual signal in the mRNA, still to be identified, ensures that this tRNA recognizes only the few UGA codons, within certain genes, that specify selenocysteine. In effect, UGA doubles as a codon for both

termination and (very occasionally) selenocysteine. This particular code expansion has a dedicated tRNA, as described above, but it lacks a dedicated cognate aminoacyl-tRNA synthetase. The process works for selenocysteine, but one might consider it an intermediate step in the evolution of a complete new codon definition.

Pyrrolysine is found in a group of anaerobic archaea called methanogens (see Box 22-1). These organisms produce methane as a required part of their metabolism, and the Methanosarcinaceae group can use methylamines as substrates for methanogenesis.

Producing methane from monomethylamine requires the enzyme monomethylamine methyltransferase. The gene encoding this enzyme has an in-frame UAG termination codon. The structure of the methyltransferase was elucidated in 2002, revealing the presence of the novel amino acid pyrrolysine at the position specified by the UAG codon. Subsequent experiments demonstrated that—unlike selenocysteine—pyrrolysine was attached directly to a dedicated tRNA by a cognate pyrrolysyl-tRNA synthetase. These cells produce pyrrolysine via a metabolic pathway that remains to be elucidated. The overall system has all the hallmarks of an established codon assignment, although it only works for UAG codons in this particular gene. As in the case of selenocysteine, there are probably contextual signals that direct this tRNA to the correct UAG codon. Can scientists match this evolutionary feat?

Modification of proteins with various functional groups can provide important insights into the activity and/or structure of the proteins.

However, protein modification is often quite laborious. For example, an investigator who wishes to attach a new group to a particular Cys residue will have to somehow block the other Cys residues that may be present on the same protein. If one could instead adapt the genetic code to enable a cell to insert a modified amino acid at a particular location in a protein, the process could be rendered much more convenient. Peter Schultz and coworkers have done just that. To develop a new codon assignment, one again needs a new aminoacyl-tRNA synthetase and a novel cognate tRNA, both adapted to work only with a particular new amino acid. Efforts to create such an “unnatural” code expansion initially focused on *E. coli*. The codon UAG was chosen as the best target for

Barnase gene Cells containing MjtRNATY' variants aminoacylated by endogenous tRNA synthetases die. Survivors have MjtRNATY' variants that are not aminoacylated. MjTyrRS gene B-lactamase gene Grow in medium containing ampicillin. Cells live only if they contain MjtRNATyr variants aminoacylated by MjTyrRS. FIGURE 1 Selecting MjtRNA™ variants that function only with the tyrosyl-tRNA synthetase MjTyrRS. The sequence of the gene encoding Mj interact with MjTyrRS (red dots). The mutagenized plasmids are introions of MjtRNA™ varis, represented by the six cells shown here. The toxic barnase gene, RNA™, on a plasmid, is randomized at 11 positions that do not duced into E. coli cells to create a library of mil an engineered to include the sequence TAG so that its transcript includes UAG codons, is provided on a separate plasmid, providing a negative ection. If this gene is expressed, the cells die. It can only be expressed if the MjtRNA™ variant expressed by that particular cell is MjtRNATY gene 27.2 Protein Synthesis 1125 A tRNA expression Randomize MjtRNATY" sequence at 11 positions, transform cells to create library. Add plasmid encoding engineered barnase gene Negative selection Remove barnase plasmid. Add plasmid encoding MjTyrRS and engineered B-lactamase gene. Positive selection (Continued on next page) aminoacylated by endogenous (E. coli) aminoacyl-tRNA synthetases, inserting an amino acid instead of stopping translation. Another gene, encoding B-lactamase, and also engineered with TAG sequences to produce UAG stop codons, is provided on yet another plasmid that also expresses the gene encoding MjTyrRS. This serves as a means of positive selection for the remaining MjtRNA™ variants. Those variants that are aminoacylated by MjTyrRS allow expression of the B-lactamase gene, which allows cells to grow on ampicillin. Multiple rounds of negative and positive selection yield the best MjtRNA™ variants that are aminoacylated uniquely by MjTyrRS and used efficiently in translation.

1126 Protein Metabolism BOX 27-3 Natural and Unnatural Expansion of the Genetic Code (Continued) encoding a new amino acid. UAG is the least used of the three termination codons, and strains with tRNAs selected to recognize UAG (see Box 27-4) do not exhibit growth defects. To create the new tRNA and tRNA synthetase, the genes for a tyrosyl-tRNA and its cognate tyrosyl-tRNA synthetase were taken from the archaeon *Methanococcus jannaschii* (MjtRNATM and MyTyrRS). MjTyrRS does not bind to the anticodon loop of MjtRNA^{'TM}, allowing the anticodon loop to be modified to CUA (complementary to UAG) without affecting the interaction. Because the archaeal and bacterial systems are orthologous, the modified archaeal components could be transferred to *E. coli* cells without disrupting the intrinsic translation system of the cells. First, the gene encoding MjtRNA^{'TM} had to be modified to generate an ideal product tRNA—one that was not recognized by any aminoacyl-tRNA synthetases endogenous to *E. coli*, but was aminoacylated by MjTyrRS. Finding such a variant could be accomplished via a series of negative and positive selection cycles designed to efficiently sift through variants of the tRNA gene (Fig. 1). Parts of the MjtRNATM sequence were randomized, allowing creation of a library of cells that each expressed a different version of the tRNA. A gene encoding barnase (a ribonuclease toxic to *E. coli*) was engineered so that its mRNA transcript contained several UAG codons, and this gene was also introduced into the cells on a plasmid. If the MjtRNATM variant expressed in a particular cell in the library was aminoacylated by an endogenous tRNA synthetase, it would express the barnase gene and that cell would die (a negative selection). Surviving cells would contain tRNA variants that were not aminoacylated by endogenous tRNA synthetases, but could potentially be aminoacylated by MjTyrRS. A positive selection (Fig. 1) was then set up by engineer

FIGURE 2 A sampling of unnatural amino acids that have been added to the genetic code. These unnatural amino acids add uniquely reactive chemical groups such as (a) a ketone, (b) an azide, (c) a photocrosslinker (a functional group designed to form a covalent bond with n H₂N—CH in the B-lactamase gene (which confers resistance to the antibiotic ampicillin) so that its transcript contained several UAG codons and introducing this gene into the cells along with the gene encoding MjTyrRSs. Those MjtRNATM variants that could be aminoacylated

by MjTyrRS allowed growth on ampicillin only when MyTyrRS was also expressed in the cell. Several rounds of this negative and positive selection scheme identified a new MjtRNATM variant that was not affected by endogenous enzymes, was aminoacylated by MjTyrRSs, and functioned well in translation. Second, the M7TyrRS had to be modified to recognize the new amino acid. The gene encoding MyTyrRS was now mutagenized to create a large library of variants. Variants that would aminoacylate the new MjtRNATM variant with endogenous amino acids were eliminated using the barnase gene selection. A second positive selection (similar to the ampicillin selection above) was carried out so that cells would survive only if the MjtRNATM variant was aminoacylated only in the presence of the unnatural amino acid. Several rounds of negative and positive selection generated a cognate tRNA synthetase-tRNA pair that recognized only the unnatural amino acid. These components were then renamed to reflect the unnatural amino acid used in the selection. Using this approach, many *Æ. coli* strains have been constructed, each capable of incorporating one particular unnatural amino acid into a protein in response to a UAG codon. The same approach has been used to artificially expand the genetic code of yeast and even mammalian cells. Over 30 different amino acids (Fig. 2) can be introduced site-specifically and efficiently into cloned proteins in this way. The result is an increasingly useful and flexible tool kit with which to advance the study of protein structure and function.

co COO- COOH, N—CH H₂N—CH CH₃, CH₃, CH₃, CH₃, SH (d) (e) (f) a nearby group when activated by light), (d) a highly fluorescent amino acid, (e) an amino acid with a heavy atom (Br) for use in crystallography, and (f) a long-chain cysteine analog that can form extended disulfide bonds.

BOX 27-3 Natural and Unnatural Expansion of the Genetic Code (Continued)

encoding a new amino acid. UAG is the least used of the three termination codons, and strains with tRNAs selected to recognize UAG (see Box 27-4) do not exhibit growth defects. To create the new tRNA and tRNA synthetase, the genes for a tyrosyl-tRNA and its cognate tyrosyl-tRNA synthetase were taken from the archaeon *Methanococcus jannaschii* (*Mj*tRNA^{Tyr} and *Mj*TyrRS). *Mj*TyrRS does not bind to the anticodon loop of *Mj*tRNA^{Tyr}, allowing the anticodon loop to be modified to CUA (complementary to UAG) without affecting the interaction. Because the archaeal and bacterial systems are orthologous, the modified archaeal components could be transferred to *E. coli* cells without disrupting the intrinsic translation system of the cells.

First, the gene encoding *Mj*tRNA^{Tyr} had to be modified to generate an ideal product tRNA—one that was not recognized by any aminoacyl-tRNA synthetases endogenous to *E. coli*, but was aminoacylated by *Mj*TyrRS. Finding such a variant could be accomplished via a series of negative and positive selection cycles designed to efficiently sift through variants of the tRNA gene (Fig. 1). Parts of the *Mj*tRNA^{Tyr} sequence were randomized, allowing creation of a library of cells that each expressed a different version of the tRNA. A gene encoding barnase (a ribonuclease toxic to *E. coli*) was engineered so that its mRNA transcript contained several UAG codons, and this gene was also introduced into the cells on a plasmid. If the *Mj*tRNA^{Tyr} variant expressed in a particular cell in the library was aminoacylated by an endogenous tRNA synthetase, it would express the barnase gene and that cell would die (a negative selection). Surviving cells would contain tRNA variants that were not aminoacylated by endogenous tRNA synthetases, but could potentially be aminoacylated by *Mj*TyrRS. A positive selection (Fig. 1) was then set up by engineer-

ing the β -lactamase gene (which confers resistance to the antibiotic ampicillin) so that its transcript contained several UAG codons and introducing this gene into the cells along with the gene encoding *Mj*TyrRS. Those *Mj*tRNA^{Tyr} variants that could be aminoacylated by *Mj*TyrRS allowed growth on ampicillin only when *Mj*TyrRS was also expressed in the cell. Several rounds of this negative and positive selection scheme identified a new *Mj*tRNA^{Tyr} variant that was not affected by endogenous enzymes, was aminoacylated by *Mj*TyrRS, and functioned well in translation.

Second, the *Mj*TyrRS had to be modified to recognize the new amino acid. The gene encoding *Mj*TyrRS was now mutagenized to create a large library of variants. Variants that would aminoacylate the new *Mj*tRNA^{Tyr} variant with endogenous amino acids were eliminated using the barnase gene selection. A second positive selection (similar to the ampicillin selection above) was carried out so that cells would survive only if the *Mj*tRNA^{Tyr} variant was aminoacylated only in the presence of the unnatural amino acid. Several rounds of negative and positive selection generated a cognate tRNA synthetase-tRNA pair that recognized only the unnatural amino acid. These components were then renamed to reflect the unnatural amino acid used in the selection.

Using this approach, many *E. coli* strains have been constructed, each capable of incorporating one particular unnatural amino acid into a protein in response to a UAG codon. The same approach has been used to artificially expand the genetic code of yeast and even mammalian cells. Over 30 different amino acids (Fig. 2) can be introduced site-specifically and efficiently into cloned proteins in this way. The result is an increasingly useful and flexible tool kit with which to advance the study of protein structure and function.

FIGURE 2 A sampling of unnatural amino acids that have been added to the genetic code. These unnatural amino acids add uniquely reactive chemical groups such as **(a)** a ketone, **(b)** an azide, **(c)** a photo-crosslinker (a functional group designed to form a covalent bond with

a nearby group when activated by light), **(d)** a highly fluorescent amino acid, **(e)** an amino acid with a heavy atom (Br) for use in crystallography, and **(f)** a long-chain cysteine analog that can form extended disulfide bonds.

Stage 2: A Specific Amino Acid Initiates Protein Synthesis

Protein synthesis begins at the amino-terminal end and proceeds by the stepwise addition of amino acids to the carboxyl-terminal end of the growing polypeptide, as determined by Howard Dintzis in 1961 (Fig. 27-24). The AUG initiation codon thus specifies an amino-terminal methionine residue. Although methionine has only one codon, (5')AUG, all organisms have two tRNAs for methionine. One is used exclusively when (5')AUG is the initiation codon for protein synthesis. The other is used to code for a Met residue in an internal position in a polypeptide. The distinction between an initiating (5')AUG and an internal one is straightforward. In bacteria, the two types of tRNA specific for methionine are designated tRNA^{TM*} and tRNATM. The amino acid incorporated in response to the (5')AUG initiation codon is Nformylmethionine (fMet). It arrives at the ribosome as N-formylmethionyl-tRNA^{TM*} (fMet-tRNA^{TM*}), which is formed in two successive reactions. First, methionine is attached to tRNA^{TM*} by the Met-tRNA synthetase (which in *E. coli* aminoacylates both tRNA^{TM*} and tRNATM): Methionine + tRNA^{TM*} + ATP $\rightarrow$ Met-tRNA^{TM*} + AMP + PP; Direction of chain growth Amino terminus Carboxyl terminus 4 min 7 min 16 min 60 min — 146 Residue number

FIGURE 27-24 Proof that polypeptides grow by addition of amino acid residues to the carboxyl end: the Dintzis experiment. Reticulocytes (immature erythrocytes) actively synthesizing hemoglobin were incubated with radioactive leucine (selected because it occurs frequently in both the α - and β -globin chains). Samples of completed α chains were isolated from the reticulocytes at various times afterward, and the distribution of radioactivity was determined. The dark red zones show the portions of completed α -globin chains containing radioactive Leu residues. At 4 min, only a few residues at the carboxyl end of α -globin were labeled, because the only complete globin chains with incorporated label after 4 min were those that had nearly completed synthesis at the time the label was added. With longer incubation times, successively longer segments of the polypeptide contained labeled residues, always in a block at the carboxyl end of the chain. The unlabeled end of the polypeptide (the amino terminus) was thus defined as the initiating end, which means that polypeptides grow by successive addition of amino acids to the carboxyl end.

27.2 Protein Synthesis 1127 Next, a transformylase transfers a formyl

group from N^o-formyltetrahydrofolate to the amino group of the Met residue: N^o-Formyltetrahydrofolate + Met-tRNA^{TM*}t —> tetrahydrofolate + f{Met-tRNA^{TM*}. The transformylase is more selective than the Met-tRNA synthetase; it is specific for Met residues attached to tRNA^{TM*} presumably recognizing some unique structural feature of that tRNA. By contrast, Met-tRNATM inserts methionine in interior positions in polypeptides. H COO | i ani ia O CH; N-Formylmethionine Addition of the N-formyl group to the amino group of methionine by the transformylase prevents fMet from entering interior positions in a polypeptide while also allowing fMet-tRNA^{TM*} to be bound at a specific ribosomal initiation site that accepts neither Met-tRNA^{TM*} nor any other aminoacyl-tRNA. In eukaryotic cells, all polypeptides synthesized by cytosolic ribosomes begin with a Met residue (rather than fMet), but, again, the cell uses a specialized initiating tRNA that is distinct from the tRNATM used at (5')AUG codons at interior positions in the mRNA. Polypeptides synthesized by mitochondrial and chloroplast ribosomes, however, begin with N-formylmethionine. This strongly supports the view that mitochondria and chloroplasts originated from bacterial ancestors that were symbiotically incorporated into precursor eukaryotic cells at an early stage of evolution (see Fig. 1-38). How can the single (5')AUG codon determine whether a starting N-formylmethionine (or methionine, in eukaryotes) or an interior Met residue is ultimately inserted? The details of the initiation process provide the answer. The Three Steps of Initiation The initiation of polypeptide synthesis in bacteria requires (1) the 30S ribosomal subunit, (2) the mRNA coding for the polypeptide to be made, (3) the initiating f{Met-tRNA^{TM*}, (4) a set of three proteins called initiation factors (IF-1, IF-2, and IF-3), (5) GTP, (6) the 50S ribosomal subunit, and (7) Mg²⁺. Formation of the initiation complex takes place in three steps (Fig. 27-25). In step 1 the 30S ribosomal subunit binds two initiation factors, IF-1 and IF-3. Factor IF-3 prevents the 30S and 50S subunits from combining prematurely. The mRNA then binds to the 30S subunit. The initiating (5')AUG is guided to its correct position by the Shine-Dalgarno sequence (named for Australian researchers John Shine and Lynn Dalgarno, who identified it) in the

1128 Protein Metabolism ©, 6 The 30S subunit binds IF-1 and mRNA IF-3, then the mRNA. Shine-Dalgarno ~ sequence 5' GTP. am ® tRNA ow / Anticodon (2) IF-2—GTP binds the 30S subunit and recruits fMet-tRNA[™]Met, which base-pairs with the start codon. 50S subunit GDP + P, 6-6-0 The 50S subunit associates, IF-2 hydrolyzes GTP, and IF-1, IF-2, and IF-3 dissociate, leaving the initiation complex. Initiation complex 3' FIGURE 27-25 Formation of the initiation complex in bacteria. The complex forms in three steps (described in the text) at the expense of the hydrolysis of GTP to GDP and P; IF-1, IF-2, and IF-3 are initiation factors. E designates the exit site, P the peptidyl site, and A the aminoacyl site. Here the anticodon of the tRNA is oriented 3' to 5', left to right, as in Figure 27-8 but opposite to the orientation in Figures 27-21 and 27-23. mRNA. This consensus sequence is an initiation signal of four to nine purine residues, 8 to 13 bp to the 5' side of the initiation codon (Fig. 27-26a). The sequence base-pairs with a complementary pyrimidine-rich sequence near the 3' end of the 16S rRNA of the 30S ribosomal subunit (Fig. 27-26b). This mRNA-rRNA interaction positions the initiating (5')AUG sequence of the mRNA in the precise position on the 30S subunit where it is required for initiation of translation. The particular (5')AUG where fMet-tRNA[™]Met is to be bound is distinguished from other methionine codons by its proximity to the Shine-Dalgarno sequence in the mRNA. Bacterial ribosomes have three sites that bind tRNAs, the aminoacyl (A) site, the peptidyl (P) site, and the exit (E) site. The A and P sites bind to aminoacyl-tRNAs, whereas the E site binds only to uncharged tRNAs that have completed their task on the ribosome. Both the 30S and the 50S subunits contribute to the characteristics of the A and P sites, whereas the E site is largely confined to the 50S subunit. The initiating (5') AUG is positioned at the P site, the only site to which fMet-tRNA[™]Met can bind (Fig. 27-25). The fMet-tRNA[™]Met is the only aminoacyl-tRNA that binds first to the P site; during the subsequent elongation stage, all other incoming aminoacyl-tRNAs (including the Met-tRNA[™] that binds to interior AUG codons) bind first to the A site and only subsequently to the P and E sites. The E site is the site from which the “uncharged” tRNAs leave during elongation. Factor IF-1 binds at the A site and prevents tRNA binding at this site during initiation. In step © of the initiation process (Fig. 27-25), the complex consisting of the 30S ribosomal subunit, IF-3,

and mRNA is joined by both GTP-bound IF-2 and the initiating fMet-tRNA^{TM*}. The anticodon of this tRNA now pairs correctly with the mRNA's initiation codon. In step © this large complex combines with the 50S ribosomal subunit; simultaneously, the GTP bound to IF-2 is hydrolyzed to GDP and P_i, which are released from the complex. All three initiation factors depart from the ribosome at this point. Completion of the steps in Figure 27-25 produces a functional 70S ribosome called the initiation complex, containing the mRNA and the initiating fMet-tRNA^{TM*}. The correct binding of the fMet-tRNATM to the P site in the complete 70S initiation complex is assured by at least three points of recognition and attachment: the codon-anticodon interaction involving the initiation AUG fixed in the P site, interaction between the Shine-Dalgarno sequence in the mRNA and the 16S rRNA, and binding interactions between the ribosomal P site and the fMet-tRNA^{TM*}. The initiation complex is now ready for elongation. Initiation in Eukaryotic Cells Translation is generally similar in eukaryotic and bacterial cells; most of the significant differences are in the number of components and in

(a) Alignment of the initiating AUG (shaded in green) at its correct location on the 30S ribosomal subunit depends in part on upstream Shine-Dalgarno sequences (light red). Portions of the mRNA transcripts of five bacterial genes are shown. Note mechanistic details. The initiation process in eukaryotes is outlined in Figure 27-27. Eukaryotic mRNAs are bound to the ribosome as a complex with a number of specific binding proteins. Eukaryotic cells have at least 12 initiation factors. Initiation factors eIF1A and eIF3 are the functional homologs of the bacterial IF-1 and IF-3, binding to the 40S subunit in step @ and blocking tRNA binding to the A site and premature joining of the large and small ribosomal subunits, respectively. The factor eIF1 binds to the E site. The charged initiator tRNA is bound by the initiation factor eIF2, which also has bound GTP. In step @ this ternary complex binds to the 40S ribosomal subunit, along with two other proteins involved in later steps, eIF5 (not shown in Fig. 27-27) and eIF5B. This creates a 43S preinitiation complex. The mRNA binds to the eIF4F complex, which, in step ©, mediates its association with the 43S preinitiation complex. The eIF4F complex is made up of eIF4E (binding to the 5' cap), eIF4A (an ATPase and RNA helicase), and eIF4G (a linker protein). The eIF4G protein binds to eIF3 and eIF4E to provide the first link between the 43S preinitiation complex and the mRNA. The eIF4G also binds to the poly(A) binding protein (PABP) at the 3' end of the mRNA, circularizing the mRNA (Fig. 27-28) and facilitating the translational regulation of gene expression, as described in Chapter 28. The addition of the mRNA and its associated factors creates a 48S complex. This complex scans the bound mRNA, starting at the

5' cap, until an AUG codon is encountered. The scanning process (step @ in Fig. 27-27) the unusual example of the *E. coli* LacI protein, which initiates with a GUG (Val) codon (see Box 27-1). In *E. coli*, AUG is the start codon in approximately 91% of the genes, with GUG (7%) and UUG (2%) assuming this role more rarely. (b) The Shine-Dalgarno sequence of the mRNA pairs with a sequence near the 3' end of the 16S rRNA. may be facilitated by the RNA helicase of eIF4A and another bound factor (eIF4B, not shown in Fig. 27-27) whose precise molecular activity is not understood. Once the initiating AUG site is encountered, the 60S ribosomal subunit associates with the complex in step ©, accompanied by the release of many of the initiation factors. This requires the activity of eIF5 and eIF5B. The eIF5 protein promotes the GTPase activity of eIF2, producing an eIF2-GDP complex with reduced affinity for the initiator tRNA. The eIF5B protein is homologous to the bacterial IF-2. It hydrolyzes its bound GTP and triggers dissociation of eIF2-GDP and other initiation factors, followed closely by the association of the 60S subunit. This completes formation of the initiation complex. The roles of the various bacterial and eukaryotic initiation factors in the overall process are summarized in Table 27-8. The mechanism by which these proteins act is an important area of investigation.

Stage 3: Peptide Bonds Are Formed in the Elongation Stage

The third stage of protein synthesis is elongation. Again, we begin with bacterial cells. Elongation requires (1) the initiation complex described above, (2) aminoacyl-tRNAs, (3) a set of three soluble cytosolic proteins called elongation factors (EF-Tu, EF-Ts, and EF-G in bacteria), and (4) GTP. Cells use three steps to add

1130 Protein Metabolism GTP (2) 3A 5! Anticodon

FIGURE 27-27 Initiation of protein synthesis in eukaryotes. The five steps are described in the text. Eukaryotic initiation factors mediate the association of first the charged initiator tRNA to form a 43S complex and **FIGURE 27-28 Circularization of the mRNA in the eukaryotic initiation complex.** The 3' and 5' ends of eukaryotic mRNAs are linked by the eIF4F complex of proteins. The eIF4E subunit binds to the 5' cap, and the eIF4G protein binds to the poly(A) binding protein (PABP) at the 3' end of the mRNA. The eIF4G protein also binds to eIF3, linking the circularized mRNA to the 40S subunit of the ribosome. Scanning 43S preinitiation complex 60S subunit then the mRNA (with the 5' cap shown in red) to form a 48S complex. The final initiation complex is formed as the 60S subunit associates, coupled with the release of most of the initiation factors. each amino acid residue, and the steps are repeated as many times as there are residues to be added.

Elongation Step 1: Binding of an Incoming Aminoacyl-tRNA In the first step of the elongation cycle (Fig. 27-29), the appropriate incoming aminoacyl-tRNA binds to a complex of GTP-bound EF-Tu. The resulting aminoacyltRNA-EF-Tu-GTP complex binds to the A site of the 70S initiation complex. The GTP is hydrolyzed and an EF-Tu-GDP complex is released from the 70S ribosome. The EF-Tu-GTP complex is regenerated in a process involving EF-Ts and GTP.

Elongation Step 2: Peptide Bond Formation A peptide bond is now formed between the two amino acids bound by their tRNAs to the A and P sites on the ribosome. This occurs by the transfer of the initiating N-formylmethionyl group from its tRNA to the amino group of the second

Protein Factors Required for Initiation of Translation in Bacterial and Eukaryotic Cells

Factor Function

Bacterial IF-1 Prevents premature binding of tRNAs to A site
IF-2 Facilitates binding of f{Met-tRNA^{TM*} to 30S ribosomal subunit
IF-3 Binds to 30S subunit; prevents premature association of 50S subunit; enhances specificity of P site for {Met-tRNA^{TM*}

Eukaryotic eIF1 Binds to the E site of the 40S subunit; facilitates interaction between eIF2-tRNA-GTP ternary complex and the 40S subunit
eIF1A Homolog of bacterial IF-1; prevents premature binding of tRNAs to A site
eIF2 GTPase; facilitates binding of eIF2B*, eIF3 eIF4F eIF4A eIF4B eIF4E eIF4G elfo” eIF5b initiating Met-tRNATM to 40S ribosomal subunit
First factors to bind 40S subunit; facilitate subsequent steps

Complex consisting of eIF4E, eIF4A, and eIF4G RNA helicase activity; removes secondary structure in the mRNA to permit binding to 40S subunit; part of the eIF4F complex
Binds to mRNA; facilitates scanning of mRNA to locate the first AUG
Binds to the 5' cap of mRNA; part of the eIF4F complex
Binds to eIF4E and to poly(A) binding protein (PABP); part of the eIF4F complex
Promotes dissociation of several other initiation factors from 40S subunit as a prelude to association of 60S subunit to form 80S initiation complex

GTPase homologous to bacterial IF-2; promotes dissociation of initiation factors prior to final ribosome assembly

*Not shown in Figure 27-27. 27.2 Protein Synthesis 1131 Incoming second aminoacyltRNA GTP hydrolysis Tu —GTP and accommodation 7 GTP 6) 3!

FIGURE 27-29 First elongation step in bacteria: binding of the second aminoacyl-tRNA. The second aminoacyl-tRNA (AA;) enters the A site of he ribosome bound to GTP-bound EF-Tu (shown here as Tu). Binding of he second aminoacyl-tRNA to the A site is accompanied by hydrolysis of he GTP to GDP and P; and release of the EF-Tu-GDP complex from the ribosome. The bound GDP is released when the EF-Tu-GDP complex binds o EF-Ts, and EF-Ts is subsequently released when another molecule of GTP binds to EF-Tu. This recycles EF-Tu and makes it available to repeat he cycle. Accommodation involves a change in the second tRNA conformation that pulls its aminoacyl end into the peptidyl transferase site.

1132 Protein Metabolism 3' FIGURE 27-30 Second elongation step in bacteria: formation of the first peptide bond. The peptidyl transferase catalyzing this reaction is the 23S rRNA ribozyme. The N-formylmethionyl group is transferred to the amino group of the second aminoacyl-tRNA in the A site, forming a dipeptidyl-tRNA. At this stage, both tRNAs bound to the ribosome shift position in amino acid, now in the A site (Fig. 27-30). The amino group of the amino acid in the A site acts as a nucleophile, displacing the tRNA in the P site to form the peptide bond. This reaction produces a dipeptidyl-tRNA in the A site, and the now "uncharged" (deacylated) tRNA^{TM*} remains bound to the P site. The tRNAs then shift to a hybrid binding state, with elements of each spanning two different sites on the ribosome, as shown in Figure 27-30. The enzymatic activity that catalyzes peptide bond formation has historically been referred to as peptidyl transferase and was widely assumed to be intrinsic to one or more of the proteins in the large ribosomal subunit. We now know that this reaction is catalyzed by the 23S rRNA, adding to the known catalytic repertoire of ribozymes. This discovery has interesting implications for the evolution of life (see Box 27-2).

Elongation Step 3: Translocation In the final step of the elongation cycle, translocation, the ribosome moves one codon toward the 3' end of the mRNA (Fig. 27-31a). This movement shifts the anticodon of the dipeptidyl-tRNA, which is still attached to the second codon of the mRNA, from the A site to the P site, and shifts the deacylated tRNA from the P site to the E site, from where the tRNA is released into the cytosol. The third codon of the mRNA now lies in the A site and the Peptide bond formation at the 50S subunit to take up a hybrid binding state. The uncharged tRNA shifts so that its 3' and 5' ends are in the E site. Similarly, the 3' and 5' ends of the peptidyl tRNA shift to the P site. The anticodons remain in the P and A sites. Note the involvement of the 2'-hydroxyl group of the 3'-terminal adenosine as a general acid-base catalyst in this reaction.

second codon in the P site. Movement of the ribosome along the mRNA requires EF-G (also known as translocase) and the energy provided by hydrolysis of another molecule of GTP. A change in the three-dimensional conformation of the entire ribosome results in its movement along the mRNA. Because the structure of EF-G mimics the structure of the EF-Tu-tRNA complex (Fig. 27-31b), EF-G can

bind the A site and presumably displace the peptidyl-tRNA. After translocation, the ribosome, with its attached dipeptidyl-tRNA and mRNA, is ready for the next elongation cycle and attachment of a third amino acid residue. This process occurs in the same way as addition of the second residue (as shown in Figs 27-29, 27-30, and 27-31). For each amino acid residue correctly added to the growing polypeptide, two GTPs are hydrolyzed to GDP and P; as the ribosome moves from codon to codon along the mRNA toward the 3' end. The polypeptide remains attached to the tRNA of the most recent amino acid to be inserted. This association maintains the functional connection between the information in the mRNA and its decoded polypeptide output. At the same time, the ester linkage between this tRNA and the carboxyl terminus of the growing polypeptide activates the terminal carboxyl group for nucleophilic attack by the incoming amino acid to form a new peptide bond (Fig. 27-30). As the existing ester linkage between

27.2 Protein Synthesis 1133 the polypeptide and tRNA is broken during peptide bond formation, the linkage between the polypeptide and the information in the mRNA persists, because each newly added amino acid is still attached to its tRNA. The elongation cycle in eukaryotes is quite similar to that in bacteria. Three eukaryotic elongation factors (eEF1a, eEF1B γ , and eEF2) have functions analogous to those of the bacterial elongation factors (EF-Tu, EF-Ts, and EF-G, respectively). Eukaryotic ribosomes do not have an E site; uncharged tRNAs are expelled directly from the P site. Proofreading on the Ribosome The GTPase activity of EF-Tu during the first step of elongation in bacterial cells (Fig. 27-29) makes an important contribution to the rate and fidelity of the overall biosynthetic process. Both the EF-Tu-GTP and EF-Tu-GDP complexes exist for a few milliseconds before they dissociate. These two intervals provide opportunities for the codon-anticodon interactions to be proofread. Incorrect aminoacyl-tRNAs normally dissociate from the A site during one of these periods. If the GTP analog guanosine 5'-O-(8-thiotriphosphate) (GTP γ S) is used in place of GTP, hydrolysis is

FIGURE 27-31 Third elongation step in bacteria: translocation. (a) The ribosome moves one codon toward the 3' end of the mRNA, using energy provided by hydrolysis of GTP bound to EF-G (translocase). The dipeptidyl-tRNA is now entirely in the P site, leaving the A site open for the incoming (third) aminoacyl-tRNA. The uncharged tRNA later dissociates from the E site, and the elongation cycle begins again. (b) The structure of EF-G mimics the structure of EF-Tu complexed with tRNA. Shown here are (left) EF-Tu complexed with tRNA (PDB ID 1B23) and (right) EF-G complexed with GDP (PDB ID 1DAR). The carboxyl-terminal part of EF-G mimics the structure of the anticodon loop of tRNA in both shape and charge distribution. EF-Tu (b)

1134 Protein Metabolism slowed, improving the fidelity (by increasing the proofreading intervals) but reducing the rate of protein synthesis. Guanosine 5'-O-(3-thiotriphosphate) Q (GTPyS) N 0 | o l i i a n O j i O j O i O (OJ ion D The process of protein synthesis (including the characteristics of codon-anticodon pairing already described) has clearly been optimized through evolution to balance the requirements for speed and fidelity. Improved fidelity might diminish speed, whereas increases in speed would probably compromise fidelity. And, recall that the proofreading mechanism on the ribosome establishes only that the proper codon-anticodon pairing has taken place, not that the correct amino acid is attached to the tRNA. If a tRNA is successfully aminoacylated with the wrong amino acid (as can be done experimentally), this incorrect amino acid is efficiently incorporated into a protein in response to whatever codon is normally recognized by the tRNA. BOX 27-4 When a mutation produces a termination codon in the interior of a gene, translation is prematurely halted and the incomplete polypeptide is usually inactive. These are called nonsense mutations. The gene can be restored to normal function if a second mutation either (1) converts the misplaced termination codon to a codon specifying an amino acid or (2) suppresses the effects of the termination codon. Such restorative mutations are called nonsense suppressors; they generally involve mutations in tRNA genes to produce altered (suppressor) tRNAs that can recognize the termination codon and insert an amino acid at that position. Most known suppressor tRNAs have single base substitutions in their anticodons. Suppressor tRNAs constitute an experimentally induced variation in the genetic code to allow the reading of what are usually termination codons, much like the naturally occurring code variations described in Box 27-1. Nonsense suppression does not completely disrupt normal information transfer in a cell, because the cell usually has several copies of each tRNA gene; some of these duplicate genes are weakly expressed and account for only a minor part of the cellular pool of a particular tRNA. Suppressor mutations usually involve a "minor" tRNA, leaving the major tRNA to read its codon normally. Stage 4: Termination of Polypeptide Synthesis Requires a Special Signal Elongation continues until the ribosome adds the last amino acid coded by the mRNA. Termination, the fourth stage of polypeptide synthesis, is signaled by the presence of

one of three termination codons in the mRNA (UAA, UAG, UGA), immediately following the final coded amino acid. Mutations in a tRNA anticodon that allow an amino acid to be inserted at a termination codon are generally deleterious to the cell (Box 27-4). In bacteria, once a termination codon occupies the ribosomal A site, three termination factors, or release factors—the proteins RF-1, RF-2, and RF-3—contribute to (1) hydrolysis of the terminal peptidyl-tRNA bond, (2) release of the free polypeptide and the last tRNA, now uncharged, from the P site, and (8) dissociation of the 70S ribosome into its 30S and 50S subunits, ready to start a new cycle of polypeptide synthesis (Fig. 27-32). RF-1 recognizes the termination codons UAG and UAA, and RF-2 recognizes UGA and UAA. Either RF-1 or RF-2 (depending on which codon is present) binds at a termination codon and induces peptidyl transferase to transfer the growing polypeptide to a water molecule rather than to another amino acid. The release factors have domains thought to mimic the structure of tRNA, as shown for the elongation factor EF-G in Figure 27-31b. The specific function of Induced Variation in the Genetic Code: Nonsense Suppression For example, *E. coli* has three identical genes for tRNA, each producing a tRNA with the anticodon (5')GUA. One of these genes is expressed at relatively high levels and thus its product represents the major tRNA[™] species; the other two genes are transcribed in only small amounts. A change in the anticodon of the tRNA product of one of these duplicate tRNA[™] genes, from (5')GUA to (5')CUA, produces a minor tRNA[™] species that will insert tyrosine at UAG stop codons. This insertion of tyrosine at UAG is carried out inefficiently, but it can produce enough full-length protein from a gene with a nonsense mutation to allow the cell to survive. The major tRNA[™] continues to translate the genetic code normally for the majority of proteins. The mutation that leads to creation of a suppressor tRNA does not always occur in the anticodon. The suppression of UGA nonsense codons generally involves the tRNA[™]? that normally recognizes UGG. The alteration that allows it to read UGA (and insert Trp residues at these positions) is a G to A change at position 24 (in an arm of the tRNA somewhat removed from the anticodon); this tRNA can now recognize both UGG and UGA. A similar change is found in tRNAs involved in the most common naturally occurring variation in the genetic code (UGA = Trp; see Box 27-1).

BOX 27-4 Induced Variation in the Genetic Code: Nonsense Suppression

When a mutation produces a termination codon in the interior of a gene, translation is prematurely halted and the incomplete polypeptide is usually inactive. These are called nonsense mutations. The gene can be restored to normal function if a second mutation either (1) converts the misplaced termination codon to a codon specifying an amino acid or (2) suppresses the effects of the termination codon. Such restorative mutations are called **nonsense suppressors**; they generally involve mutations in tRNA genes to produce altered (suppressor) tRNAs that can recognize the termination codon and insert an amino acid at that position. Most known suppressor tRNAs have single base substitutions in their anticodons.

Suppressor tRNAs constitute an experimentally induced variation in the genetic code to allow the reading of what are usually termination codons, much like the naturally occurring code variations described in Box 27-1. Nonsense suppression does not completely disrupt normal information transfer in a cell, because the cell usually has several copies of each tRNA gene; some of these duplicate genes are weakly expressed and account for only a minor part of the cellular pool of a particular tRNA. Suppressor mutations usually involve a “minor” tRNA, leaving the major tRNA to read its codon normally.

For example, *E. coli* has three identical genes for tRNA^{Tyr}, each producing a tRNA with the anticodon (5')GUA. One of these genes is expressed at relatively high levels and thus its product represents the major tRNA^{Tyr} species; the other two genes are transcribed in only small amounts. A change in the anticodon of the tRNA product of one of these duplicate tRNA^{Tyr} genes, from (5')GUA to (5')CUA, produces a minor tRNA^{Tyr} species that will insert tyrosine at UAG stop codons. This insertion of tyrosine at UAG is carried out inefficiently, but it can produce enough full-length protein from a gene with a nonsense mutation to allow the cell to survive. The major tRNA^{Tyr} continues to translate the genetic code normally for the majority of proteins.

The mutation that leads to creation of a suppressor tRNA does not always occur in the anticodon. The suppression of UGA nonsense codons generally involves the tRNA^{Trp} that normally recognizes UGG. The alteration that allows it to read UGA (and insert Trp residues at these positions) is a G to A change at position 24 (in an arm of the tRNA somewhat removed from the anticodon); this tRNA can now recognize *both* UGG and UGA. A similar change is found in tRNAs involved in the most common naturally occurring variation in the genetic code (UGA = Trp; see Box 27-1).

Peptidyl-tRNA link hydrolyzed Components dissociate “a @ ne T

FIGURE 27-32 Termination of protein synthesis in bacteria. Termination occurs in response to a termination codon in the A site. First, a release factor, RF (RF-1 or RF-2, depending on which termination codon is present), binds to the A site. This leads to hydrolysis of the ester linkage between the nascent polypeptide and the tRNA in the P site and release of the completed polypeptide. Finally, the mRNA, deacylated tRNA, and release factor leave the ribosome, which dissociates into its 30S and 50S subunits, aided by ribosome recycling factor (RRF), IF-3, and energy provided by EF-G-mediated GTP hydrolysis. The 30S subunit complex with IF-3 is ready to begin another cycle of translation (see Fig. 27-25). RF-3 has not been firmly established, although it is thought to release the ribosomal subunit. In eukaryotes, a single release factor, eRF, recognizes all three termination codons.

27.2 Protein Synthesis

1135 Ribosome recycling leads to dissociation of the translation components.

The release factors dissociate from the posttermination complex (with an uncharged tRNA in the P site) and are replaced by EF-G and a protein called ribosome recycling factor (RRF; M, 20,300). Hydrolysis of GTP by EF-G leads to dissociation of the 50S subunit from the 30S-tRNA—mRNA complex. EF-G and RRF are replaced by IF-3, which promotes the dissociation of the tRNA. The mRNA is then released. The complex of IF-3 and the 30S subunit is then ready to initiate another round of protein synthesis (Fig. 27-25).

Energy Cost of Fidelity in Protein Synthesis

Synthesis of a protein true to the information specified in its mRNA requires energy. Formation of each aminoacyl-tRNA uses two high-energy phosphate groups. An additional ATP is consumed each time an incorrectly activated amino acid is hydrolyzed by the deacylation activity of an aminoacyl-tRNA synthetase as part of its proofreading activity. A GTP is cleaved to GDP and P_i during the first elongation step, and another during the translocation step. Thus, on average, the energy derived from the hydrolysis of more than four NTPs to NDPs is required for the formation of each peptide bond of a polypeptide. This represents an exceedingly large thermodynamic “push” in the direction of synthesis: at least $4 \times 30.5 \text{ kJ/mol} = 122 \text{ kJ/mol}$ of phosphodiester bond energy to generate a peptide bond, which has a standard free energy of hydrolysis of only about -21 kJ/mol . The net free-energy change during peptide bond synthesis

is thus -101 kJ/mol . Proteins are information-containing polymers. The biochemical goal is not simply the formation of a peptide bond but the formation of a peptide bond between two specified amino acids. Each of the high-energy phosphate compounds expended in this process plays a critical role in maintaining proper alignment between each new codon in the mRNA and its associated amino acid at the growing end of the polypeptide. This energy permits very high fidelity in the biological translation of the genetic message of mRNA into the amino acid sequence of proteins.

Rapid Translation of a Single Message by Polysomes Large clusters of 10 to 100 ribosomes that are very active in protein synthesis can be isolated from both eukaryotic and bacterial cells. Electron micrographs show a fiber between adjacent ribosomes in the cluster, which is called a polysome (Fig. 27-33a). The connecting strand is a single molecule of mRNA that is being translated simultaneously by many closely spaced ribosomes, allowing the highly efficient use of the mRNA. In bacteria, transcription and translation are tightly coupled. Messenger RNAs are synthesized and translated in the same $5' \rightarrow 3'$ direction. Ribosomes begin translating the $5'$ end of the mRNA before transcription is complete (Fig. 27-33b). The situation is quite different in eukaryotic cells, where newly transcribed mRNAs must leave the nucleus before they can be translated.

and translation in bacteria. (a) Electron micrograph of polysomes
forming during the transcription of a segment of DNA from *E. coli*.
Each mRNA is being translated by many ribosomes simultaneously.
The nascent polypeptide chains forming on the ribosomes are
difficult to see under the spreading conditions used to prepare the
samples shown in these electron micrographs. The arrow marks the
approximate beginning of the gene that is being transcribed. (b)
Each mRNA is translated by ribosomes while it is still being
transcribed from DNA by RNA polymerase. This is possible because
the mRNA in bacteria does not have to be transported from a
nucleus to the cytoplasm before encountering ribosomes. In this
schematic diagram the ribosomes are depicted as smaller than the
RNA polymerase. In reality the ribosomes ($M, 2.7 \times 10^6$) are an
order of magnitude larger than the RNA polymerase ($M, 3.9 \times 10^5$).
Bacterial mRNAs generally exist for just a few minutes (p. 1084)
before they are degraded by nucleases. In order to maintain high
rates of protein synthesis, the mRNA for a given protein or set of
proteins must be made continuously and translated with maximum
efficiency. The short lifetime of mRNAs in bacteria allows a rapid
cessation of synthesis when the protein is no longer needed. Stage
5: Newly Synthesized Polypeptide Chains Undergo Folding and
Processing In the final stage of protein synthesis, the nascent
polypeptide chain is folded and processed into its biologically active
form. During or after its synthesis, the polypeptide progressively
assumes its native conformation, with the formation of appropriate
hydrogen bonds and van der Waals, ionic, and hydrophobic
interactions. In this way the linear, or one-dimensional, genetic
message in the mRNA is converted into the three-dimensional
structure of the protein. Some newly made proteins, bacterial,
archaeal, and eukaryotic, do not attain their final biologically active
conformation until they have been altered by one or more
processing reactions called posttranslational modifications. Amino-
Terminal and Carboxyl-Terminal Modifications The first residue
inserted in all polypeptides is N-formylmethionine (in bacteria) or
methionine (in eukaryotes). However, the formyl group, the amino-
terminal Met residue, and often additional amino-terminal (and, in

some cases, carboxylterminal) residues may be removed enzymatically in formation of the final functional protein. In as many as 50% of eukaryotic proteins, the amino group of the aminoterminal residue is N-acetylated after translation. Carboxylterminal residues are also sometimes modified. Loss of Signal Sequences As we shall see in Section 27.3, the 15 to 30 residues at the amino-terminal end of some proteins play a role in directing the protein to its ultimate destination in the cell. Such signal sequences are eventually removed by specific peptidases. Modification of Individual Amino Acids The hydroxyl groups of certain Ser, Thr, and Tyr residues of some proteins are enzymatically phosphorylated by ATP (Fig. 27-34a); the phosphate groups add negative charges to these polypeptides. The functional significance of this modification varies from one protein to the next. For example, the milk protein casein has many phosphoserine groups that bind Ca^{2+} . Calcium, phosphate, and amino acids are all valuable to suckling young, so casein efficiently provides three essential nutrients. And as we have seen in numerous instances, phosphorylation-dephosphorylation cycles regulate the activity of many enzymes and regulatory proteins. Extra carboxyl groups may be added to Glu residues of some proteins. For example, the blood-clotting protein prothrombin contains a number of γ -carboxyglutamate residues (Fig. 27-34b) in its amino-terminal region, introduced by an enzyme that requires vitamin K. These carboxyl groups bind Ca^{2+} , which is required to initiate the clotting mechanism. Monomethyl- and dimethyllysine residues (Fig. 27-34c) occur in some muscle proteins and in cytochrome c. The calmodulin of most species contains one trimethyllysine residue at a specific position. In other proteins, the carboxyl groups of some Glu residues undergo methylation, removing their negative charge. Attachment of Carbohydrate Side Chains The carbohydrate side chains of glycoproteins are attached covalently during or after synthesis of the polypeptide. In some glycoproteins, the carbohydrate side chain is attached enzymatically to Asn residues (N-linked oligosaccharides), in others to Ser or Thr residues (O-linked oligosaccharides) (see Fig. 7-30). Many proteins that function extracellularly, as well as the lubricating proteoglycans that coat mucous

linkage is shown in red. The Ras protein is the product of the ras
oncogene. membranes, contain oligosaccharide side chains (see Fig.
7-28). Addition of Isoprenyl Groups A number of eukaryotic
proteins are modified by the addition of groups derived from
isoprene (isoprenyl groups). A thioether bond is formed between
the isoprenyl group and a Cys residue of the protein (see Fig.
11-15). The isoprenyl groups are derived from pyrophosphorylated
intermediates of the cholesterol biosynthetic pathway (see Fig.
21-35), such as farnesyl pyrophosphate (Fig. 27-35). Proteins
modified in this way include the Ras proteins (small G proteins),
which are products of the ras oncogenes and proto-oncogenes, and
the trimeric G proteins (both discussed in Chapter 12), as well as
lamins, proteins found in the nuclear matrix. The isoprenyl group
helps to anchor the protein in a membrane. The transforming
(carcinogenic) activity of the ras oncogene is lost when
isoprenylation of the Ras protein is blocked, a finding that has
stimulated interest in identifying inhibitors of this posttranslational
modification pathway for use in cancer chemotherapy. Addition of
Prosthetic Groups Many proteins require for their activity
covalently bound prosthetic groups. Two examples are the biotin
molecule of acetyl-CoA carboxylase and the heme group of
hemoglobin or cytochrome c. Proteolytic Processing Many proteins
are initially synthesized as large, inactive precursor polypeptides
that are proteolytically trimmed to form their smaller, active forms.
Examples include proinsulin, some viral proteins, and proteases
such as chymotrypsinogen and trypsinogen (see Fig. 6-38).

Formation of Disulfide Cross-Links After folding into their native conformations, some proteins form intrachain or interchain disulfide bridges between Cys residues. In eukaryotes, disulfide bonds are common in proteins to be exported from cells. The cross-links formed in this way help to protect the native conformation of the protein molecule from denaturation in the extracellular environment, which can differ greatly from intracellular conditions and is generally oxidizing.

1138 Protein Metabolism Protein Synthesis Is Inhibited by

Many Antibiotics and Toxins Protein synthesis is a central function in cellular physiology and is the primary target of many naturally occurring antibiotics and toxins. Except as noted, these antibiotics inhibit protein synthesis in bacteria. The differences between bacterial and eukaryotic protein synthesis, though in some cases subtle, are sufficient that most of the compounds discussed below are relatively harmless to eukaryotic cells. Natural selection has favored the evolution of compounds that exploit minor differences in order to affect bacterial systems selectively, such that these biochemical weapons are synthesized by some microorganisms and are extremely toxic to others. Because nearly every step in protein synthesis can be specifically inhibited by one antibiotic or another, antibiotics have become valuable tools in the study of protein biosynthesis. Puromycin, made by the mold *Streptomyces alboniger*, is one of the best-understood inhibitory antibiotics. Its structure is very similar to the 3' end of an aminoacyl-tRNA, enabling it to bind to the ribosomal A site and participate in peptide bond formation, producing peptidylpuromycin (Fig. 27-36). However, because puromycin resembles only the 3' end of the tRNA, it does not engage in translocation and dissociates from the ribosome shortly after it is linked to the carboxyl terminus of the peptide. This prematurely terminates polypeptide synthesis. Tetracyclines inhibit protein synthesis in bacteria by blocking the A site on the ribosome, preventing the binding of aminoacyl-tRNAs. Chloramphenicol inhibits protein synthesis by bacterial (and mitochondrial and chloroplast) ribosomes by blocking peptidyl transfer; it does not affect cytosolic protein synthesis in eukaryotes. Conversely, cycloheximide blocks the peptidyl transferase of 80S eukaryotic ribosomes but not that of 70S bacterial (and mitochondrial and chloroplast) ribosomes. Streptomycin, a basic trisaccharide, causes misreading of the genetic code (in bacteria) at relatively low concentrations and inhibits initiation at higher concentrations.

CH₃ HC O to CH o" CON ~O H Cycloheximide NH

Streptomycin Several other inhibitors of protein synthesis are notable because of their toxicity to humans and other mammals. Diphtheria toxin (M, 58,330) catalyzes the ADP-ribosylation of a diphthamide (a modified histidine) residue of eukaryotic elongation factor eEF2, thereby inactivating it. Ricin (V, 29,895), an extremely toxic protein of the castor bean, inactivates the 60S subunit of eukaryotic ribosomes by depurinating a specific adenosine in 23S rRNA. Ricin was used in the infamous 1978 murder of BBC journalist and Bulgarian dissident Georgi Markov, presumably by the Bulgarian secret police. Using a syringe hidden at the end of an umbrella, a member of the secret police injected Markov in the leg with a ricin-infused pellet. He died 4 days later.

SUMMARY 27.2 Protein Synthesis > Protein synthesis occurs on the ribosomes, which consist of protein and rRNA. Bacteria have 70S ribosomes, with a large (50S) and a small (30S) subunit. Eukaryotic ribosomes are significantly larger (80S) and contain more proteins. > Transfer RNAs have 73 to 93 nucleotide residues, some of which have modified bases. Each tRNA has an amino acid arm with the terminal sequence CCA(3') to which an amino acid is esterified, an anticodon arm, a T ψ C arm, and a D arm; some tRNAs have a fifth arm. The anticodon is responsible for the specificity of interaction between the aminoacyl-tRNA and the complementary mRNA codon.

> The growth of polypeptides on ribosomes begins with the amino-terminal amino acid and proceeds by successive additions of new residues to the carboxyl-terminal end.

27.3 Protein Targeting and Degradation 1139 > Protein synthesis occurs in five stages. 1. Amino acids are activated by specific aminoacyl-tRNA synthetases in the cytosol. These enzymes catalyze the formation of aminoacyl-tRNAs, with simultaneous cleavage of ATP to AMP and PP_i. The fidelity of protein synthesis depends on the accuracy of this reaction, and some of these enzymes carry out proofreading steps at separate active sites. 2. In bacteria, the initiating aminoacyl-tRNA in all proteins is N-formylmethionyl-tRNA^{fMet}, Initiation of protein synthesis involves formation of a complex between the 30S ribosomal subunit, mRNA, GTP, fMet-tRNA^{fMet}, three initiation factors, and the 50S subunit; GTP is hydrolyzed to GDP and P_i. 3. In the elongation steps, GTP and elongation factors are required for binding the incoming aminoacyl-tRNA to the A site on the

ribosome. In the first peptidyl transfer reaction, the fMet residue is transferred to the amino group of the incoming aminoacyl-tRNA. Movement of the ribosome along the mRNA then translocates the dipeptidyl-tRNA from the A site to the P site, a process requiring hydrolysis of GTP. Deacylated tRNAs dissociate from the ribosomal E site. 4. After many such elongation cycles, synthesis of the polypeptide is terminated with the aid of release factors. At least four high-energy phosphate equivalents (from ATP and GTP) are required to generate each peptide bond, an energy investment required to guarantee fidelity of translation. 5. Polypeptides fold into their active, three-dimensional forms. Many proteins are further processed by posttranslational modification reactions. > Many well-studied antibiotics and toxins inhibit some aspect of protein synthesis.

27.3 Protein Targeting and Degradation

The eukaryotic cell is made up of many structures, compartments, and organelles, each with specific functions that require distinct sets of proteins and enzymes. These proteins (with the exception of those produced in mitochondria and plastids) are synthesized on ribosomes in the cytosol, so how are they directed to their final cellular destinations? We are now beginning to understand this complex and fascinating process. Proteins destined for secretion, integration in the plasma membrane, or inclusion in lysosomes generally share the first few steps of a pathway that begins in the endoplasmic reticulum. Proteins destined for mitochondria, chloroplasts, or the nucleus use three separate mechanisms. And proteins destined for the cytosol simply remain where they are synthesized.

1140 Protein Metabolism The most important element in many of these targeting pathways is a short sequence of amino acids called a signal sequence, whose function was first postulated by Günter Blobel and colleagues in 1970. The signal sequence directs a protein to its appropriate location in the cell and, for many proteins, is removed during transport or after the protein has reached its final destination. In proteins slated for transport into mitochondria, chloroplasts, or the ER, the signal sequence is at the amino terminus of a newly synthesized polypeptide. In many cases, the targeting capacity of particular signal sequences has been confirmed by fusing the signal sequence from one protein to a second protein and showing that the signal directs the second protein to the location where the first protein is normally found. The selective degradation of proteins no longer needed by the cell also relies largely on a set of molecular signals embedded in each protein's structure. In this concluding section we examine protein targeting and degradation, emphasizing the underlying signals and molecular regulation that are so crucial to cellular metabolism. Except where noted, the focus is now on eukaryotic cells.

Günter Blobel Posttranslational Modification of Many Eukaryotic Proteins Begins in the Endoplasmic Reticulum Perhaps the best-characterized targeting system begins in the ER. Most lysosomal, membrane, or secreted proteins have an amino-terminal signal sequence (Fig. 27-37) that marks them for translocation into the lumen of the ER; hundreds of such signal sequences have been determined. The carboxyl terminus of the signal sequence is defined by a cleavage site, where protease action removes the sequence after the protein is imported into the ER. Signal sequences vary in length from 13 to 36 amino acid residues, but all have the Human influenza virus A Met Lys Ala Lys Leu Leu Human preproinsulin Bovine growth hormone Met Met Ala Ala Gly Pro Arg Thr Ser L Bee promellitin Met Lys Phe Leu Val Asn *Drosophila* glue protein

FIGURE 27-37 Amino-terminal signal sequences of some eukaryotic proteins that direct their translocation into the ER. The hydrophobic core (yellow) is preceded by one or more basic residues (blue). Note the polar following features: (1) about 10 to 15 hydrophobic amino acid residues; (2) one or more positively charged residues, usually near the amino terminus, preceding the hydrophobic sequence; and (8) a short sequence at the carboxyl terminus (near the cleavage

site) that is relatively polar, typically having amino acid residues with short side chains (especially Ala) at the positions closest to the cleavage site. As originally demonstrated by George Palade, proteins with these signal sequences are synthesized on ribosomes attached to the ER. The signal sequence itself helps to direct the ribosome to the ER, as illustrated by steps a through c in Figure 27-38.

a The targeting pathway begins with initiation of protein synthesis on free ribosomes. b The signal sequence appears early in the synthetic process, because it is at the amino terminus, which as we have seen is synthesized first. c As it emerges from the ribosome, the signal sequence—and the ribosome itself—is bound by the large signal recognition particle (SRP); SRP then binds GTP and halts elongation of the polypeptide when it is about 70 amino acids long and the signal sequence has completely emerged from the ribosome. d The GTP-bound SRP now directs the ribosome (still bound to the mRNA) and the incomplete polypeptide to GTP-bound SRP receptors in the cytosolic face of the ER; the nascent polypeptide is delivered to a peptide translocation complex in the ER, which may interact directly with the ribosome. e SRP dissociates from the ribosome, accompanied by hydrolysis of GTP in both SRP and the SRP receptor. f Elongation of the polypeptide now resumes, with the ATP-driven translocation complex feeding the growing polypeptide into the ER lumen until the complete protein has been synthesized. g The signal sequence is removed by a signal peptidase within the ER lumen; h the ribosome dissociates and i is recycled.

Signal sequence Cytosol Ribosome ~. | translocation complex , receptor Endoplasmic ~ ~ reticulum FIGURE 27-38

Directing eukaryotic proteins with the appropriate signals to the endoplasmic reticulum. This process involves the SRP cycle and translocation and cleavage of the nascent polypeptide. The steps are described in the text. SRP is a rod-shaped complex containing a 300 nucleotide RNA (7SL-RNA) and six different proteins (combined M, 325,000). One protein subunit of SRP binds directly to the signal sequence. Glycosylation Plays a Key Role in Protein Targeting In the ER lumen, newly synthesized proteins are further modified in several ways. Following the removal of signal sequences, polypeptides are folded, disulfide bonds formed, and many proteins glycosylated to form glycoproteins. In many glycoproteins the linkage to their oligosaccharides is through Asn residues. These N-linked oligosaccharides are diverse (Chapter 7), but the pathways by which they form have a common first step. A 14 residue core oligosaccharide is built up in a stepwise fashion, then transferred from a dolichol phosphate donor molecule to certain Asn residues in the protein (Fig. 27-39). The transferase is on the luminal face of the ER and thus cannot catalyze glycosylation of cytosolic proteins. After transfer, the core oligosaccharide is trimmed and elaborated in different ways on different proteins, but all N-linked oligosaccharides retain a pentasaccharide core derived from the original 14 residue oligosaccharide. Several antibiotics act by interfering with one or more steps in this process and have aided in elucidating the steps of protein glycosylation. The best characterized is tunicamycin, which mimics the structure of UDP-N-acetylglucosamine and blocks the first step of the process (Fig. 27-39, step @). A few proteins are O-glycosylated in the ER, but most O-glycosylation occurs in the Golgi complex or in the cytosol (for proteins that do not enter the ER).  occur on the cytosolic face o brane (mechanism not shown), and @
 completion of the core oligosaccharide occurs within the lumen of
 the ER. The precursors that contribute additional mannose and
 glucose residues to the growing oligosaccharide in the lumen are
 dolichol phosphate derivatives. In the first step in the construction
 of the N-linked oligosaccharide moiety of a glycoprotein, @,
 Suitably modified proteins can now be moved to a variety of
 intracellular destinations. Proteins travel from the ER to the Golgi
 complex in transport vesicles (Fig. 27-40). In the Golgi complex,
 oligosaccharides are O-linked to some proteins, and N-linked
 oligosaccharides are further modified. By mechanisms not yet fully
 understood, the Golgi complex also sorts proteins and sends them to
 their final destinations. The processes that segregate proteins
 targeted for secretion from those targeted for the plasma membrane
 or lysosomes must distinguish among these proteins on the basis of
 structural features other than signal sequences, which were
 removed in the ER lumen. This sorting process is best understood in
 the case of hydrolases destined for transport to lysosomes. On
 arrival of a hydrolase (a glycoprotein) in the Golgi complex, an as
 yet undetermined feature (sometimes called a signal patch) of the
 three-dimensional structure of hydrolase is recognized by a
 phosphotransferase, which phosphorylates certain mannose residues
 in oligosaccharide (Fig. 27-41). The presence of one or more
 mannose 6-phosphate residues in its N-linked reticulum @ the core
 oligosaccharide is transferred from dolichol phosphate to an Asn
 residue of the protein within the ER lumen. The core
 oligosaccharide is then further modified in the ER and the Golgi
 complex in pathways that differ for different proteins. The five
 sugar residues shown surrounded by a beige screen (after step @)

are retained in the final structure of all N-linked oligosaccharides.

@ The released dolichol pyrophosphate is again translocated so that the pyrophosphate is on the cytosolic face of the ER, then @@ a phosphaphosphate. e is hydrolytically removed to regenerate dolichol oligosaccharide is the structural signal that targets a protein to lysosomes. A receptor protein in the membrane of the Golgi complex recognizes the mannose 6-phosphate signal and binds the hydrolase so marked. Vesicles containing these receptor-hydrolase complexes bud from the trans side of the Golgi complex and make their way to sorting vesicles. Here, the receptor-hydrolase complex dissociates in a process facilitated by the lower pH in the vesicle and by phosphatase-catalyzed removal of phosphate groups from the mannose 6-phosphate residues. The receptor is then recycled to the Golgi complex, and vesicles containing the hydrolases bud from the sorting vesicles and move to the lysosomes. In cells treated with tunicamycin (Fig. 27-39, step @), hydrolases that should be targeted to lysosomes are instead secreted, confirming that the N-linked oligosaccharide plays a key role in targeting these enzymes to lysosomes. The pathways that target proteins to mitochondria and chloroplasts also rely on amino-terminal signal sequences. Although mitochondria and chloroplasts contain DNA, most of their proteins are encoded by

 appropriate organelle. Unlike other targeting pathways, however,
 the mitochondrial and chloroplast pathways begin only after a
 precursor protein has been completely synthesized and released
 from the ribosome. Precursor proteins destined for mitochondria or
 chloroplasts are bound by cytosolic chaperone proteins and
 delivered to receptors on the exterior surface of the target
 organelle. Specialized translocation mechanisms then transport the
 protein to its final destination in the organelle, after which the
 signal sequence is removed. Signal Sequences for Nuclear Transport
 Are Not Cleaved Molecular communication between the nucleus
 and the cytosol requires the movement of macromolecules through
 nuclear pores. RNA molecules synthesized in the nucleus are

1144 Protein Metabolism into the nucleus and assembled into 60S and 40S ribosomal subunits in the nucleolus; completed subunits are then exported back to the cytosol. A variety of nuclear proteins (RNA and DNA polymerases, histones, topoisomerases, proteins that regulate gene expression, and so forth) are synthesized in the cytosol and imported into the nucleus. This traffic is modulated by a complex system of molecular signals and transport proteins that is gradually being elucidated. In most multicellular eukaryotes, the nuclear envelope breaks down at each cell division, and once division is completed and the nuclear envelope reestablished, the dispersed nuclear proteins must be reimported. To allow this repeated nuclear importation, the signal sequence that targets a protein to the nucleus—the nuclear localization sequence (NLS)—is not removed after the protein arrives at its destination. An NLS, unlike other signal sequences, may be located almost anywhere along the primary sequence of the protein.

(a) Cytosol Nuclear protein a AS er SP Og? Importin AAS S { Nuclear envelope = — Nuclear pore Nucleoplasm

FIGURE 27-42 Targeting of nuclear proteins. (a) @ A protein with an appropriate nuclear localization signal (NLS) is bound by a complex of importin α and B. @ The resulting complex binds to a nuclear pore and translocates. © Inside the nucleus, dissociation of importin B is promoted by the binding of Ran-GTP. @ Importin α binds to Ran-GTP and CAS (cellular apoptosis susceptibility protein), releasing the nuclear protein. © importin α and B and CAS are transported out of the nucleus and recycled. They are released in the cytosol when Ran hydrolyzes its bound GTP. NLSs can vary considerably, but many consist of four to eight amino acid residues and include several consecutive basic (Arg or Lys) residues. Nuclear importation is mediated by a number of proteins that cycle between the cytosol and the nucleus (Fig. 27-42), including importin α and B and a small GTPase known as Ran (Ras-related nuclear protein). A heterodimer of importin α and β functions as a soluble receptor for proteins targeted to the nucleus, with the α subunit binding NLS-bearing proteins in the cytosol. The complex of the NLS-bearing protein and the importin docks at a nuclear pore and is translocated through the pore by an energy-dependent mechanism. In the nucleus, the importin B is bound by Ran GTPase, releasing importin β from the imported protein. Importin β is bound by Ran and by CAS (cellular apoptosis

susceptibility protein) and separated from the NLS-bearing protein. Importin α and β , in their complexes with Ran and CAS, are then exported from the nucleus. Ran $\odot$ Ran-GDP is bound by NTF2, and transported back into the nucleus. $\oplus$ RanGEF promotes the exchange of GDP for GTP in the nucleus, and Ran-GTP is ready to process another NLS-bearing protein-importin complex. (b) Scanning electron micrograph of the surface of the nuclear envelope, showing numerous nuclear pores. The nuclear pore complex is one of the largest molecular aggregates in the cell (M, $\sim 5 \times 10^6$). It is made up of multiple copies of over 30 different proteins.

hydrolyzes GTP in the cytosol to release the importins, which are then free to begin another importation cycle. Ran itself is also cycled back into the nucleus by the binding of Ran-GDP to nuclear transport factor 2 (NTF2). Inside the nucleus, the GDP bound to Ran is replaced with GTP through the action of Ran guanosine nucleotide-exchange factor (RanGEF; see Box 12-2).

Bacteria Also Use Signal Sequences for Protein Targeting Bacteria can target proteins to their inner or outer membranes, to the periplasmic space between these membranes, or to the extracellular medium. They use signal sequences at the amino terminus of the proteins

Most proteins exported from *Æ. coli* make use of the pathway shown in Figure 27-44. Following translation, a protein to be exported may fold only slowly, the aminoterminal signal sequence impeding the folding. The soluble chaperone protein SecB

binds to the protein's signal sequence or other features of its incompletely folded structure. The bound protein is then delivered to SecA, a protein associated with the inner surface of the plasma membrane. SecA acts as both a receptor and a translocating ATPase. Released from SecB and bound to SecA, the protein is delivered to a translocation complex in the membrane, made up of SecY, E, and G, and is translocated stepwise through the membrane at the SecYEG complex.

FIGURE 27-44 Model for protein export in bacteria.

@ A newly translated polypeptide binds to the cytosolic chaperone protein SecB, which **@** delivers it to SecA, a protein associated with the translocation complex (SecYEG) in the bacterial cell membrane. **@** SecB is released, and SecA inserts itself into the membrane, forcing about 20 amino acid residues of the protein to be exported through the translocation complex. **@** Hydrolysis of an ATP by SecA provides the energy for a conformational change that causes SecA to withdraw from the membrane, releasing the polypeptide. **@** SecA binds another ATP, and the next stretch of 20 amino acid residues is pushed across the membrane through the translocation complex. Steps **@** and **@** are repeated until **@** the entire protein has passed through and is released to the periplasm. The electrochemical potential across the membrane (denoted by + and —) also provides some of the driving force required for protein translocation.

1146 Protein Metabolism Clathrin-independent endocytosis Caveolin-independent endocytosis FIGURE 27-45 Summary of endocytosis Clathrin- and caveolin- pathways in eukaryotic cells. Pathways independent pathways dependent on clathrin or caveolin make use of Dynamin and Caveolin. Clathrin WY MH, JF x , Caveosome Uncoating in lengths of about 20 amino acid residues. Each step is facilitated by the hydrolysis of ATP, catalyzed by SecA. An exported protein is thus pushed through the membrane by a SecA protein located on the cytoplasmic surface, not pulled through the membrane by a protein on the periplasmic surface. This difference may simply reflect the need for the translocating ATPase to be where the ATP is. The transmembrane electrochemical potential can also provide energy for translocation of the protein, by an as yet unknown mechanism. Although most exported bacterial proteins use this pathway, some follow an alternative pathway that uses signal recognition and receptor proteins homologous to components of the eukaryotic SRP and SRP receptor (Fig. 27-38). Cells Import Proteins by Receptor-Mediated Endocytosis Some proteins are imported into eukaryotic cells from the surrounding medium; examples include low-density lipoprotein (LDL), the iron-carrying protein transferrin, peptide hormones, and circulating proteins destined for degradation. There are several importation pathways (Fig. 27—45). In one path, proteins bind to receptors in invaginations of the membrane called coated pits, which concentrate endocytic receptors in preference to other cell-surface proteins. The pits are coated on their cytosolic side with a lattice of the protein clathrin, which forms closed polyhedral structures (Fig. 27-46). The clathrin lattice grows as more receptors are occupied by target proteins. Eventually, a complete membrane-bounded endocytic vesicle is pinched off the plasma membrane with the aid of the large GTPase dynamin, and enters the cytoplasm. The clathrin is quickly removed by uncoating enzymes, and the vesicle fuses with an endosome. ATPase activity in the endosomal membranes reduces the pH therein, facilitating dissociation of receptor. The GTPase dynamin to pinch vesicles from the plasma membrane. Some pathways do not use clathrin or caveolin; some of these make use of dynamin and some do not. (c) FIGURE 27-46 Clathrin. (a) Three light (L) chains (M, 35,000) and three heavy (H) chains (M, 180,000) of the (HL); clathrin unit, organized

as a three-legged structure called a triskelion. (b) Triskelions tend to assemble into polyhedral lattices. (c) Electron micrograph of a coated pit on the cytosolic face of the plasma membrane of a fibroblast. Clusters of clathrin triskelions are seen as dark spots. The triskelions are bound to their target proteins. In a related pathway, caveolin causes invagination of patches of membrane containing lipid rafts associated with certain types of receptors (see Fig. 11-22). These endocytic vesicles then fuse with caveolin-containing internal structures, caveosomes, where the internalized molecules are sorted and redirected to other parts of the cell and the caveolins are prepared for recycling to the membrane surface. There

are also clathrin- and caveolin-independent pathways; some make use of dynamin and others do not. The imported proteins and receptors then go their separate ways, their fates varying with the cell and protein type. Transferrin and its receptor are eventually recycled. Some hormones, growth factors, and immune complexes, after eliciting the appropriate cellular response, are degraded along with their receptors. LDL is degraded after the associated cholesterol has been delivered to its destination, but the LDL receptor is recycled (see Fig. 21-41). Receptor-mediated endocytosis is exploited by some toxins and viruses to gain entry to cells. Influenza virus, diphtheria toxin, and cholera toxin all enter cells in this way.

Protein Degradation Is Mediated by Specialized Systems in All Cells

Protein degradation prevents the buildup of abnormal or unwanted proteins and permits the recycling of amino acids. The half-lives of eukaryotic proteins vary from 30 seconds to many days. Most proteins turn over rapidly relative to the lifetime of a cell, although a few (such as hemoglobin) can last for the life of the cell (about 110 days for an erythrocyte). Rapidly degraded proteins include those that are defective because of incorrectly inserted amino acids or because of damage accumulated during normal functioning. And enzymes that act at key regulatory points in metabolic pathways often turn over rapidly. Defective proteins and those with characteristically short half-lives are generally degraded in both bacterial and eukaryotic cells by selective ATP-dependent cytosolic systems. A second system in vertebrates, operating in lysosomes, recycles the amino acids of membrane proteins, extracellular proteins, and proteins with characteristically long half-lives. In *E. coli*, many proteins are degraded by an ATP-dependent protease called Lon (the name refers to the “long form” of proteins, observed only when this protease is absent). The protease is activated in the presence of defective proteins or those slated for rapid turnover; two ATP molecules are hydrolyzed for every peptide bond cleaved. The precise role of this ATP hydrolysis is not yet clear. Once a protein has been reduced to small inactive peptides, other ATP-independent proteases complete the degradation process. The ATP-dependent pathway in eukaryotic cells is quite different, involving the protein ubiquitin, which, as its name suggests, occurs throughout the eukaryotic kingdoms. One of the most highly conserved proteins known, ubiquitin (76 amino

acid residues) is essentially identical in organisms as different as yeasts and humans. Ubiquitin is covalently linked to proteins slated for destruction via an ATP-dependent pathway involving three separate types of enzymes, called E1 activating enzymes, E2 conjugating enzymes, and E3 ligases (Fig. 27-47).

27.3 Protein Targeting and Degradation

1147 Ubiquitin EON ji Ubiquitin —C—S H HN —Lys — Target protein O I Ubiquitin |;—C—NH—Lys—Target protein

Repeated cycles lead to attachment of additional ubiquitin. **FIGURE 27-47** Three-step pathway by which ubiquitin is attached to a protein. Two different enzyme-ubiquitin intermediates are involved. The free carboxyl group of ubiquitin's carboxyl-terminal Gly residue first becomes linked to an E1-class activating enzyme via a thioester. The ubiquitin is then transferred to an E2 conjugating enzyme. An E3 ligase ultimately catalyzes the transfer of the ubiquitin from E2 to the target, linking ubiquitin through an amide (isopeptide) bond to an ϵ -amino group of a Lys residue of the target protein. Additional cycles produce polyubiquitin, a covalent polymer of ubiquitin subunits that targets the attached protein for destruction in eukaryotes. Multiple pathways of this sort, with different protein targets, are present in most eukaryotic cells. Ubiquitinated proteins are degraded by a large complex known as the 26S proteasome (M, 2.5×10^6) (Fig. 27-48). The eukaryotic proteasome consists of two copies each of at least 32 different subunits, most of which are highly conserved from yeasts to humans. The proteasome contains two main types of subcomplexes, a barrel-like core particle and regulatory particles on either end of the barrel. The 20S core particle consists of four rings; the outer rings are formed from seven a

FIGURE 27-48 Three-dimensional structure of the eukaryotic proteasome. The 26S proteasome is highly conserved in all eukaryotes. The two subassemblies are the 20S core particle and the 19S regulatory particle, or cap. (a) (PDB ID 3L5Q) The core particle consists of four rings arranged to form a barrel-like structure. Each of the inner rings has seven different B subunits (dark brown), three of which have protease activities. The outer rings each have seven different a subunits (light brown). A regulatory particle forms a cap on each end of the core particle (gray). (b) The regulatory particle binds ubiquitinated proteins, unfolds them, and translocates them into the core particle, where they are degraded to peptides of 3 to 25 amino acid residues. subunits, and the inner rings from seven B subunits. Three of the seven subunits in each £ ring have protease activities, each with different substrate specificities. The stacked rings of the core particle form the barrellike structure within which target proteins are degraded. The 19S regulatory particle on each end of the core particle contains approximately 18 subunits, including some that recognize and bind to ubiquitinated proteins. Six of the subunits are AAA + ATPases (see Chapter 25) that probably function in unfolding the ubiquitinated proteins and translocating the unfolded polypeptide into the core particle for degradation. The 19S particle also deubiquitinates the proteins as they are degraded in the proteasome. Most cells have additional regulatory complexes that can replace the 19S particle. These alternative regulators do not hydrolyze ATP and do not bind to ubiquitin, but they are important for the degradation of particular cellular proteins. The 26S proteasome can be effectively “accessorized,” with regulatory complexes changing with changing cellular conditions. Although we do not yet understand all the signals that trigger ubiquitination, one simple signal has been found. For many proteins, the identity of the first residue that remains after removal of the amino-terminal Met residue, and any other posttranslational proteolytic processing of the amino-terminal end, has a profound influence on half-life (Table 27-9). These amino-terminal signals have been conserved over billions of years of evolution and are the same in bacterial protein degradation

systems and in the human ubiquitination pathway. More complex signals, such as the destruction box discussed in Chapter 12 (see Fig. 12-47), are also being identified. Ubiquitin-dependent proteolysis is as important for the regulation of cellular processes as for the elimination of defective proteins. Many proteins required at only one stage of the eukaryotic cell cycle are rapidly degraded by the ubiquitin-dependent pathway after completing their function. Ubiquitin-dependent destruction of cyclin is critical to cell-cycle regulation (see Fig. 12-47). The E1, E2, and E3 components of the ubiquitination pathway (Fig. 27-47) are in fact large families of proteins. Different E1, E2, and E3 enzymes exhibit different specificities for target proteins and thus regulate different cellular processes. Some of these enzymes are highly localized in certain cellular compartments, reflecting a specialized function. Not surprisingly, defects in the ubiquitination pathway have been implicated in a wide range of disease states. An inability to degrade certain proteins that activate cell division (the products of oncogenes) can lead to tumor formation, whereas a too-rapid degradation of proteins that act as tumor suppressors can have the same effect. The ineffective or overly rapid degradation of cellular proteins also appears to play a role in a range of other conditions: renal diseases, asthma, neurodegenerative disorders such as Alzheimer and Parkinson diseases (associated with the formation of characteristic proteinaceous structures in neurons), cystic fibrosis (caused in some cases by a too-rapid degradation of a chloride ion channel, with resultant loss of function; see Box 11-2), Liddle syndrome (in which a VW}

*Half-lives were measured in yeast for the B-galactosidase protein modified so that in each experiment it had a different amino-terminal residue. Half-lives may vary for different proteins and in different organisms, but this general pattern appears to hold for all organisms.

sodium channel in the kidney is not degraded, leading to excessive Na⁺ absorption and early-onset hypertension)—and many other disorders. Drugs designed to inhibit proteasome function are being developed as potential treatments for some of these conditions. In a changing metabolic environment, protein degradation is as important to a cell's survival as is protein synthesis, and much remains to be learned about these interesting pathways.

E SUMMARY 27.3 Protein Targeting and Degradation

> After synthesis, many proteins are directed to particular locations in the cell. One targeting mechanism involves a peptide signal sequence, generally found at the amino terminus of a newly synthesized protein.

> In eukaryotic cells, one class of signal sequences is recognized by the signal recognition particle (SRP), which binds the signal sequence as soon as it appears on the ribosome and transfers the entire ribosome and incomplete polypeptide to the ER. Polypeptides with these signal sequences are moved into the ER lumen as they are synthesized; once in the lumen they may be modified and moved to the Golgi complex, then sorted and sent to lysosomes, the plasma membrane, or transport vesicles.

> Proteins targeted to mitochondria and chloroplasts in eukaryotic cells, and those destined for export in bacteria, also make use of an amino-terminal signal sequence.

> Proteins targeted to the nucleus have an internal signal sequence that, unlike other signal sequences, is not cleaved once the protein is successfully targeted.

> Some eukaryotic cells import proteins by receptor-mediated endocytosis.

> All cells eventually degrade proteins, using specialized proteolytic systems. Defective proteins and those slated for rapid turnover are generally degraded by an ATP-dependent system. In eukaryotic cells, the proteins are first tagged by linkage to ubiquitin, a highly conserved protein. Ubiquitin-dependent proteolysis is carried out by proteasomes, also highly conserved, and is critical to the regulation of many cellular processes.

Problems 1. Messenger RNA Translation Predict the amino acid sequences of peptides formed by ribosomes in response to the following mRNA sequences, assuming that the reading frame begins with the first three bases in each sequence. (a) GGUCAGUCGCUCCUGAUU (b) UUGGAUGCGCCAUAUUUGCU (c) CAUGAUGCCUGUUGCUAC (d) AUGGACGAA

2. How Many Different mRNA Sequences Can Specify One Amino Acid Sequence? Write all the possible mRNA sequences that can code for the simple

tripeptide segment Leu—Met-Tyr. Your answer will give you some idea about the number of possible mRNAs that can code for one polypeptide. 3. Can the Base Sequence of an mRNA Be Predicted from the Amino Acid Sequence of Its Polypeptide Product? A given sequence of bases in an mRNA will code for one and only one sequence of amino acids in a polypeptide, if the reading frame is specified. From a given sequence of amino acid residues in a protein such as cytochrome c, can we predict the base sequence of the unique mRNA that coded it? Give reasons for your answer. 4. Coding of a Polypeptide by Duplex DNA The template strand of a segment of double-helical DNA contains the sequence (5')CTTAACACCCCTGACTTCGCGCCGTCG(3') (a) What is the base sequence of the mRNA that can be transcribed from this strand? (b) What amino acid sequence could be coded by the mRNA in (a), starting from the 5' end?

(c) If the complementary (nontemplate) strand of this DNA were transcribed and translated, would the resulting amino acid sequence be the same as in (b)? Explain the biological significance of your answer.

5. Methionine Has Only One Codon Methionine is one of two amino acids with only one codon. How does the single codon for methionine specify both the initiating residue and interior Met residues of polypeptides synthesized by *E. coli*?

6. Synthetic mRNAs The genetic code was elucidated with polyribonucleotides synthesized either enzymatically or chemically in the laboratory. Given what we now know about the genetic code, how would you make a polyribonucleotide that could serve as an mRNA coding predominantly for many Phe residues and a small number of Leu and Ser residues? What other amino acid(s) would be coded for by this polyribonucleotide, but in smaller amounts?

7. Energy Cost of Protein Biosynthesis Determine the minimum energy cost, in terms of ATP equivalents expended, required for the biosynthesis of the B-globin chain of hemoglobin (146 residues), starting from a pool including all necessary amino acids, ATP, and GTP. Compare your answer with the direct energy cost of the biosynthesis of a linear glycogen chain of 146 glucose residues in (1→4) linkage, starting from a pool including glucose, UTP, and ATP (Chapter 15). From your data, what is the extra energy cost of making a protein, in which all the residues are ordered in a specific sequence, compared with the cost of making a polysaccharide containing the same number of residues but lacking the informational content of the protein? In addition to the direct energy cost for the synthesis of a protein, there are indirect energy costs—those required for the cell to make the necessary enzymes for protein synthesis. Compare the magnitude of the indirect costs to a eukaryotic cell of the biosynthesis of linear (1→4) glycogen chains and the biosynthesis of polypeptides, in terms of the enzymatic machinery involved.

8. Predicting Anticodons from Codons Most amino acids have more than one codon and attach to more than one tRNA, each with a different anticodon. Write all possible anticodons for the four codons of glycine: (5')GGU, GGC, GGA, and GGG. (a) From your answer, which of the positions in the anticodons are primary determinants of their codon specificity in the case of glycine? (b) Which of these anticodon-codon pairings has/have a wobbly base pair? (c) In which of the anticodon-codon pairings do all three

positions exhibit strong Watson-Crick hydrogen bonding? 9. Effect of Single-Base Changes on Amino Acid Sequence Much important confirmatory evidence on the genetic code has come from assessing changes in the amino acid sequence of mutant proteins after a single base has been changed in the gene that encodes the protein.

Which of the following amino acid replacements would be consistent with the genetic code if the replacements were caused by a single base change? Which cannot be the result of a single-base mutation? Why? Problems 1151 (a) Phe—Leu (b) Lys—Ala (c) Ala—Thr (d) Phe—Lys (e) Ile—Leu (f) His—>Glu (g) Pro—Ser 10.

Resistance of the Genetic Code to Mutation The following RNA sequence represents the beginning of an open reading frame. What changes (if any) can occur at each position without generating a change in the encoded amino acid residue?

(5')AUGAUUUGCUAUCUUGGACU 11. Basis of the Sickle-Cell Mutation Sickle-cell hemoglobin has a Val residue at position 6 of the B-globin chain instead of the Glu residue found in normal hemoglobin A. Can you predict what change took place in the DNA codon for glutamate to account for replacement of the Glu residue by Val? 12. Proofreading by Aminoacyl-tRNA Synthetases The isoleucyl-tRNA synthetase has a proofreading function that ensures the fidelity of the aminoacylation reaction, but the histidyl-tRNA synthetase lacks such a proofreading function. Explain. 13.

Importance of the “Second Genetic Code” Some aminoacyl-tRNA synthetases do not recognize and bind the anticodon of their cognate tRNAs but instead use other structural features of the tRNAs to impart binding specificity. The tRNAs for alanine apparently fall into this category. (a) What features of tRNA^{Ala} are recognized by Ala-tRNA synthetase? (b) Describe the consequences of a C—G mutation in the third position of the anticodon of tRNA^{Ala}. (c) What other kinds of mutations might have similar effects? (d) Mutations of these types are never found in natural populations of organisms. Why? (Hint: Consider what might happen both to individual proteins and to the organism as a whole.) 14. The Role of Translation Factors A researcher isolates mutant variants of the bacterial translation factors IF-2, EF-Tu, and EF-G. In each case, the mutation allows proper folding of the protein and the binding of GTP but does not allow GTP hydrolysis. At what stage would translation be blocked by each mutant protein? 15. Maintaining the Fidelity of Protein Synthesis The chemical mechanisms used to

avoid errors in protein synthesis are different from those used during DNA replication. DNA polymerases use a 3'—5' exonuclease proofreading activity to remove mispaired nucleotides incorrectly inserted into a growing DNA strand. There is no analogous proofreading function on ribosomes and, in fact, the identity of an amino acid attached to an incoming tRNA and added to the growing polypeptide is never checked. A proofreading step that hydrolyzed the previously formed peptide bond after an incorrect amino acid had been inserted into a growing polypeptide (analogous to the proofreading step of DNA polymerases) would be impractical. Why? (Hint: Consider how the link between the growing polypeptide and the mRNA is maintained during elongation; see Figs 27-29 and 27-30.)

1152 Protein Metabolism 16. Predicting the Cellular Location of a Protein The gene for a eukaryotic polypeptide 300 amino acid residues long is altered so that a signal sequence recognized by SRP occurs at the polypeptide's amino terminus and a nuclear localization signal (NLS) occurs internally, beginning at residue 150. Where is the protein likely to be found in the cell? 17. Requirements for Protein Translocation across a Membrane The secreted bacterial protein OmpA has a precursor, ProOmpA, which has the amino-terminal signal sequence required for secretion. If purified ProOmpA is denatured with 8 M urea and the urea is then removed (such as by running the protein solution rapidly through a gel filtration column), the protein can be translocated across isolated bacterial inner membranes *in vitro*. However, translocation becomes impossible if ProOmpA is first allowed to incubate for a few hours in the absence of urea. Furthermore, the capacity for translocation is maintained for an extended period if ProOmpA is first incubated in the presence of another bacterial protein called trigger factor. Describe the probable function of this factor. 18. Protein-Coding Capacity of a Viral DNA The 5,386 bp genome of bacteriophage ϕ X174 includes genes for 10 proteins, designated A to K, with sizes given in the table below. How much DNA would be required to encode these 10 proteins? How can you reconcile the size of the X174 genome with its protein-coding capacity?

Protein	Amino acid residues
A	455
B	120
C	86
D	152
E	91
F	427
G	175
H	328
J	38
K	56

19. Designing Proteins by Using Randomly Generated Genes Studies of the amino acid sequence and corresponding three-dimensional structure of wild-type or mutant proteins have led to significant insights into the principles that govern protein folding. An important test of this understanding would be to design a protein based on these principles and see whether it folds as expected. Kamtekar and colleagues (1993) used aspects of the genetic code to generate random protein sequences with defined patterns of hydrophilic and hydrophobic residues. Their clever approach combined knowledge about protein structure, amino acid properties, and the genetic code to explore the factors that influence protein structure. They set out to generate a set of proteins with the simple four-helix bundle structure shown at the end of the paragraph, with a helices (shown as cylinders) connected

by segments of random coil (light red). Each α helix is amphipathic—the R groups on one side of the helix are exclusively hydrophobic (yellow) and those on the other side are exclusively hydrophilic (blue). A protein consisting of four of these helices separated by short segments of random coil would be expected to fold so that the hydrophilic sides of the helices face the solvent.

coo + + NH; NH;
coo

Four-helix bundle An amphipathic α helix (a) What forces or interactions hold the four α helices together in this bundled structure? Figure 4—4a shows a segment of α helix consisting of 10 amino acid residues. With the gray central rod as a divider, four of the R groups (purple spheres) extend from the left side of the helix and six extend from the right. (b) Number the R groups in Figure 4a, from top (amino terminus; 1) to bottom (carboxyl terminus; 10). Which R groups extend from the left side and which from the right? (c) Suppose you wanted to design this 10 amino acid segment to be an amphipathic helix, with the left side hydrophilic and the right side hydrophobic. Give a sequence of 10 amino acids that could potentially fold into such a structure. There are many possible correct answers here. (d) Give one possible double-stranded DNA sequence that could encode the amino acid sequence you chose for (c). (It is an internal portion of a protein, so you do not need to include start or stop codons.) Rather than designing proteins with specific sequences, Kamtekar and colleagues designed proteins with partially random sequences, with hydrophilic and hydrophobic amino acid residues placed in a controlled pattern. They did this by taking advantage of some interesting features of the genetic code to construct a library of synthetic DNA molecules with partially random sequences arranged in a particular pattern. To design a DNA sequence that would encode random hydrophobic amino acid sequences, the researchers began with the degenerate codon NTN, where N can be A, G, C, or T. They filled each N position by including an equimolar mixture of A, G, C, and T in the DNA synthesis reaction to generate a mixture of DNA molecules with different nucleotides at that position (see Fig. 8-35). Similarly, to encode random polar amino acid sequences, they began with the degenerate codon NAN and used an equimolar mixture of A, G, and C (but in this case, no T) to fill the N positions. (e) Which amino acids can be encoded by the NTN triplet? Are all amino acids in this set hydrophobic? Does the set include all the hydrophobic amino acids?

(f) Which amino acids can be encoded by the NAN triplet? Are all of these polar? Does the set include all the polar amino acids? (g) In creating the NAN codons, why was it necessary to leave T out of the reaction mixture? Kamtekar and coworkers cloned this library of random DNA sequences into plasmids, selected 48 that produced the correct patterning of hydrophilic and hydrophobic amino acids, and expressed these in *Æ. coli*. The next challenge was to determine whether the proteins folded as expected. It would be very time-consuming to express each protein, crystallize it, and determine its complete three-dimensional structure. Instead, the investigators used the *E. coli* protein-processing machinery to screen out sequences that led to highly defective proteins. In this initial screening, they kept only those Data Analysis Problem 1153 clones that resulted in a band of protein with the expected molecular weight on SDS polyacrylamide gel electrophoresis (see Fig. 3-18). (h) Why would a grossly misfolded protein fail to produce a band of the expected molecular weight on electrophoresis? Several proteins passed this initial test, and further exploration showed that they had the expected four-helix structure. G) Why didn't all of the random-sequence proteins that passed the initial screening test produce four-helix structures? Reference Kamtekar, S., Schiffer, J.M., Xiong, H., Babik, J.M., & Hecht, M.H. (1993) Protein design by binary patterning of polar and nonpolar amino acids. *Science* 262, 1680-1685.

Regulation of Gene Expression 28.1 Principles of Gene Regulation 1156 28.2 Regulation of Gene Expression in Bacteria 1165 28.3 Regulation of Gene Expression in Eukaryotes 1175

genome, or the perhaps 25,000 genes in the human genome, only a fraction are expressed in a cell at any given time. Some gene products are present in very large amounts: the elongation factors required for protein synthesis, for example, are among the most abundant proteins in bacteria, and ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco) of plants and photosynthetic bacteria is, as far as we know, the most abundant enzyme in the biosphere. Other gene products occur in much smaller amounts; for instance, a cell may contain only a few molecules of the enzymes that repair rare DNA lesions. Requirements for some gene products change over time. The need for enzymes in certain metabolic pathways may wax and wane as food sources change or are depleted. During development of a multicellular organism, some proteins that influence cellular differentiation are present for just a brief time in only a few cells. Specialization of cellular function can dramatically affect the need for various gene products; an example is the uniquely high concentration of a single protein—hemoglobin—in erythrocytes. Given the high cost of protein synthesis, regulation of gene expression is essential to making optimal use of available energy. The cellular concentration of a protein is determined by a delicate balance of at least seven processes, each having several potential points of regulation:

1. Synthesis of the primary RNA transcript (transcription)
2. Posttranscriptional modification of mRNA
3. Messenger RNA degradation
4. Protein synthesis (translation)
5. Posttranslational modification of proteins
6. Protein targeting and transport
7. Protein degradation

These processes are summarized in Figure 28-1. We have examined several of these mechanisms in previous chapters. Posttranscriptional modification of mRNA, by processes such as alternative splicing patterns (see Fig. 26-21) or RNA editing (see Figs 27-10, 27-12), can affect which proteins are produced from an mRNA transcript and in what amounts. A variety of nucleotide sequences in an mRNA can affect the rate of its degradation (p. 1084). Many factors affect the rate at which an mRNA is translated into a protein, as well as the posttranslational modification, targeting, and eventual degradation of that protein

(Chapter 27). Of the regulatory processes illustrated in Figure 28-1, those operating at the level of transcription initiation are particularly well-documented. These processes are a major focus of this chapter, although other mechanisms are also considered. Researchers continue to discover complex and sometimes surprising regulatory mechanisms, leading to an increasing appreciation of the importance of posttranscriptional and translational regulation, especially in eukaryotes. For many genes, the regulatory processes are elaborate and redundant and can involve a considerable investment of chemical energy. Control of transcription initiation permits the synchronized regulation of multiple genes encoding products with interdependent activities. For example, when their DNA is heavily damaged, bacterial cells require a coordinated increase in the levels of the many DNA repair enzymes. And perhaps the most sophisticated form of coordination occurs in the complex regulatory circuits that guide the development of multicellular eukaryotes, which can involve many types of regulatory mechanisms. We begin by examining the interactions between proteins and DNA that are the key to transcriptional regulation. We next discuss the specific proteins that influence the expression of specific genes, first in bacterial 1155

Seven processes that affect the steady-state concentration of a
protein. Each process has several potential points of regulation. and
then in eukaryotic cells. Information about posttranscriptional and
translational regulation is included in the discussion, where
relevant, to provide a more complete overview of the rich
complexity of regulatory mechanisms. 28.1 Principles of Gene
Regulation Genes for products that are required at all times, such as
those for the enzymes of central metabolic pathways, are expressed
at a more or less constant level in virtually every cell of a species or
organism. Such genes are often referred to as housekeeping genes.
Unvarying expression of a gene is called constitutive gene
expression. For other gene products, cellular levels rise and fall in
response to molecular signals; this is regulated gene expression.
Gene products that increase in concentration under particular
molecular circumstances are referred to as inducible; the process of
increasing their expression is induction. The expression of many of
the genes encoding DNA repair enzymes, for example, is induced by
a system of regulatory proteins that responds to high levels of DNA
damage. Conversely, gene products that decrease in concentration
in response to a molecular signal are referred to as repressible, and
the process is called repression. For example, in bacteria, ample
supplies of tryptophan lead to repression of the genes for the
enzymes that catalyze tryptophan biosynthesis. Transcription is
mediated and regulated by protein-DNA interactions, especially
those involving the protein components of RNA polymerase
(Chapter 26). We first consider how the activity of RNA polymerase
is regulated, and proceed to a general description of the proteins
participating in this regulation. We then examine the molecular
basis for the recognition of specific DNA sequences by DNA-binding
proteins. RNA Polymerase Binds to DNA at Promoters RNA
polymerases bind to DNA and initiate transcription at promoters
(see Fig. 26-5), sites generally found near points at which RNA
synthesis begins on the DNA template. The regulation of
transcription initiation often entails changes in how RNA

polymerase interacts with a promoter. The nucleotide sequences of promoters vary considerably, affecting the binding affinity of RNA polymerases and thus the frequency of transcription initiation. Some *Escherichia coli* genes are transcribed once per second, others less than once per cell generation. Much of this variation is due to differences in promoter sequence. In the absence of regulatory proteins, differences in promoter sequence may affect the frequency of transcription initiation by a factor of 1,000 or more. Most *E. coli* promoters have a sequence close to a consensus (Fig. 28-2). Mutations that result in a shift away from the consensus sequence usually decrease promoter function; conversely, mutations toward consensus usually enhance promoter function. KEY CONVENTION: By convention, DNA sequences are shown as they exist in the nontemplate strand, with the 5' terminus on the left. Nucleotides are numbered from the transcription start site, with positive numbers to the right (in the direction of transcription) and negative numbers to the left. N indicates any nucleotide. E Although housekeeping genes are expressed constitutively, the cellular concentrations of the proteins they RNA start site -35 region -10 region mRNA DNA 5' [UP element | [TTGACA TATAAT | FIGURE 28-2 Consensus sequence for many *E. coli* promoters. Most base substitutions in the —10 and —35 regions have a negative effect on promoter function. Some promoters also include the UP (upstream promoter) element (see Fig. 26-5).

encode vary widely. For these genes, the RNA polymerase — promoter interaction strongly influences the rate of transcription initiation; differences in promoter sequence allow the cell to synthesize the appropriate level of each housekeeping gene product. The basal rate of transcription initiation at the promoters of nonhousekeeping genes is also determined by the promoter sequence, but expression of these genes is further modulated by regulatory proteins. Many of these proteins work by enhancing or interfering with the interaction between RNA polymerase and the promoter. The sequences of eukaryotic promoters are more variable than their bacterial counterparts (see Fig. 26-8). The three eukaryotic RNA polymerases usually require an array of general transcription factors in order to bind to a promoter. Yet, as with bacterial gene expression, the basal level of transcription is determined by the effect of promoter sequences on the function of RNA polymerase and its associated transcription factors.

Transcription Initiation Is Regulated by Proteins That Bind to or Near Promoters At least three types of proteins regulate transcription initiation by RNA polymerase: specificity factors alter the specificity of RNA polymerase for a given promoter or set of promoters, repressors impede access of RNA polymerase to the promoter, and activators enhance the RNA polymerase—promoter interaction. We introduced bacterial specificity factors in Chapter 26 (see Fig. 26-5), although we did not refer to them by that name. The σ subunit of the *E. coli* RNA polymerase holoenzyme is a specificity factor that mediates promoter recognition and binding. Most *E. coli* promoters are recognized by a single σ subunit (M_r 70,000), σ^{70} . Under some conditions, some of the σ^{70} subunits are replaced by one of six other specificity factors. One notable case arises when the bacteria are subjected to heat stress, leading to the replacement of σ^{70} by σ^{32} (M_r 32,000). When bound to σ^{32} , RNA polymerase is directed to a specialized set of promoters with a different consensus sequence (Fig. 28-3). These promoters control the expression of a set of genes that encode proteins, including some protein chaperones (p. 146), that are part of a stress-induced system called the heat shock response. Thus, through changes in the binding affinity of the polymerase that direct it to different

28.1 Principles of Gene Regulation 1157 promoters, a set of genes involved in related processes is coordinately regulated. In

eukaryotic cells, some of the general transcription factors, in particular the TATA-binding protein (TBP; see Fig. 26-9), may be considered specificity factors. Repressors bind to specific sites on the DNA. In bacterial cells, such binding sites, called operators, are generally near a promoter. RNA polymerase binding, or its movement along the DNA after binding, is blocked when the repressor is present. Regulation by means of a repressor protein that blocks transcription is referred to as negative regulation. Repressor binding to DNA is regulated by a molecular signal (or effector), usually a small molecule or a protein, that binds to the repressor and causes a conformational change. The interaction between repressor and signal molecule either increases or decreases transcription. In some cases, the conformational change results in dissociation of a DNA-bound repressor from the operator (Fig. 28-4a). Transcription initiation can then proceed unhindered. In other cases, interaction between an inactive repressor and the signal molecule causes the repressor to bind to the operator (Fig. 28-4b). In eukaryotic cells, the binding site for a repressor may be some distance from the promoter. Binding of these repressors to their binding sites has the same effect as in bacterial cells: inhibiting the assembly or activity of a transcription complex at the promoter. Activators provide a molecular counterpoint to repressors; they bind to DNA and enhance the activity of RNA polymerase at a promoter; this is positive regulation. In bacteria, activator-binding sites are often adjacent to promoters that are bound weakly or not at all by RNA polymerase alone, such that little transcription occurs in the absence of the activator. Many eukaryotic activators bind to DNA sites, called enhancers, that are quite distant from the promoter. These activators affect the rate of transcription at a promoter that may be located thousands of base pairs away. Some activators are usually bound to DNA, enhancing transcription until dissociation of the activator is triggered by the binding of a signal molecule (Fig. 28-4c). In other cases the activator binds to DNA only after interaction with a signal molecule (Fig. 28—4d). Signal molecules can therefore increase or decrease transcription, depending on how they affect the activator. Positive regulation is particularly common in eukaryotes, as we shall see.

FIGURE 28-3 Consensus sequence for promoters that regulate expression of the *E. coli* heat shock genes. This system responds to temperature increases as well

as some other environmental stresses, resulting in the induction of a set of proteins. Binding of RNA polymerase to heat shock promoters is mediated by a specialized σ subunit of the polymerase, σ_{HSE} , which replaces σ^{70} in the RNA polymerase initiation complex.

1158 Regulation of Gene Expression (a) Negative regulation Molecular signal causes dissociation of repressor from DNA, inducing transcription. FIGURE 28-4 Common patterns of regulation of transcription initiation. Two types of negative regulation are illustrated. (a) Repressor binds to the operator in the absence of the molecular signal; the external signal causes dissociation of the repressor to permit transcription. (b) Repressor binds in the presence of the signal; the repressor dissociates and transcription ensues when the signal is removed. Positive regulation is mediated by gene activators. Again, two types are shown. (c) Activator binds in the absence of the molecular signal and transcription proceeds; when the signal is added, the activator dissociates and transcription is inhibited. (d) Activator binds in the presence of the signal; it dissociates only when the signal is removed. Note that “positive” and “negative” regulation refer to the type of regulatory protein involved: the bound protein either facilitates or inhibits transcription. In either case, addition of the molecular signal may increase or decrease transcription, depending on its effect on the regulatory protein. In eukaryotes, the distance between the binding sites of activators or repressors and promoters is bridged by looping out the DNA in between (Fig. 28-5). The looping is facilitated in some cases by proteins called archiActivator Architectural regulator binding site 5' Promoter 3' 5' Architectural regulator 3' Recruitment 5

FIGURE 28-5 The interaction between activators/repressors and RNA polymerase in eukaryotes. Eukaryotic activators and repressors often bind sites thousands of base pairs from the promoters they regulate. DNA looping, often facilitated by architectural regulators, brings the sites together. The interaction between activators and RNA polymerase is often mediated by coactivators, as shown. Repression is sometimes

mediated by repressors (described later) that bind to activators, thereby preventing the activating interaction with RNA polymerase. Structural regulators that bind to intervening sites and facilitate the looping of the DNA. Most of the eukaryotic systems involve protein activators. The actual interaction between the activators and the RNA polymerase at the promoter is often mediated by intermediary proteins called coactivators. In some instances, protein repressors may take the place of coactivators, binding to the activators and preventing the activating interaction. Many Bacterial Genes Are Clustered and Regulated in Operons Bacteria have a simple general mechanism for coordinating the regulation of genes encoding products that participate in a set of related processes: these genes are clustered on the chromosome and are transcribed together. Many bacterial mRNAs are polycistronic— multiple genes on a single transcript—and the single promoter that initiates transcription of the cluster is the

Activator Repressor binding site binding site DNA
 [Promoter [Operator] Genes transcribed as a unit Regulatory
 sequences FIGURE 28-6 Representative bacterial operon. Genes A,
 B, and C are transcribed on one polycistronic mRNA. Typical
 regulatory sequences include binding sites for proteins that either
 activate or repress transcription from the promoter. site of
 regulation for expression of all the genes in the cluster. The gene
 cluster and promoter, plus additional sequences that function
 together in regulation, are called an operon (Fig. 28-6). Operons
 that include two to six genes transcribed as a unit are common;
 some operons contain 20 or more genes. Many of the principles of
 bacterial gene expression were first defined by studies of lactose
 metabolism in *E. coli*, which can use lactose as its sole carbon
 source. In 1960, François Jacob and Jacques Monod published a
 short paper in the Proceedings of the French Academy of Sciences
 that described how two adjacent genes involved in lactose
 metabolism were coordinately regulated by a genetic element
 located at one end of the gene cluster. The genes were those for β -
 galactosidase, which cleaves lactose to galactose and glucose, and
 for galactoside permease (lactose permease, p. 416), which
 transports lactose into the cell (Fig. 28-7). The terms “operon” and
 “operator” were first introduced in this paper. With the operon
 model, gene regulation could, for the first time, be considered in
 molecular terms. Jacques Monod, 1910-1976 François Jacob The
 lac Operon Is Subject to Negative Regulation The lactose (*lac*)
 operon (Fig. 28-8a) includes the genes for β -galactosidase (*Z*),
 galactoside permease (*Y*), and thiogalactoside transacetylase (*A*).
 The last of these enzymes seems to modify toxic galactosides to
 facilitate their removal from the cell. Each of the three genes is
 preceded by a ribosome-binding site (not shown in Fig. 28-8) that
 independently directs the translation of that gene (Chapter 27).
 Regulation of the *lac* operon by the *lac* repressor protein (*Lac*)
 follows the pattern outlined in Figure 28-4a. 28.1 Principles of Gene
 Regulation 1159 The study of *lac* operon mutants has revealed
 some details of the workings of the operon’s regulatory system. In
 the absence of lactose, the *lac* operon genes are repressed.
 Mutations in the operator or in another gene, the *J* gene, result in
 constitutive synthesis of the gene products. When the *J* gene is
 defective, repression can be restored by introducing a functional *J*

gene into the cell on another DNA molecule, demonstrating that the λ gene encodes a diffusible molecule that causes gene repression. This molecule proved to be a protein, now called the Lac repressor, a tetramer of identical monomers. The operator to which it binds most tightly (O_1) abuts the transcription start site (Fig. 28-8a). The J gene is transcribed from its own promoter (P_J) independent of the lac operon genes. The lac operon has two secondary binding sites for the Lac repressor. One (O_2) is centered near position +410, within the gene encoding B-galactosidase (Z); the other (O_3) is near position -90, within the J gene. To repress the operon, the Lac repressor seems to bind to both the main operator and one of the two secondary sites, with the intervening Extracellular space

P is the promoter for the lac genes, and P_i is the promoter for the I gene. O₁ is the main operator for the lac operon; O₂ and O₃ are secondary operator sites of lesser affinity for the Lac repressor. The inverted repeat to which the Lac repressor binds in O₁ is shown in the inset. (b) The Lac repressor binds to the main operator and O₂ or O₃, apparently forming a loop in the DNA. (c) (PDB ID 2PE5) Lac repressor (shades of red) is shown bound to short, discontinuous segments of DNA (blue and orange). DNA looped out (Fig. 28-8b, c). Either binding arrangement blocks transcription initiation. Despite this elaborate binding complex, repression is not absolute. Binding of the Lac repressor reduces the rate of transcription initiation by a factor of 10⁴. If the O and O₂ sites are eliminated by deletion or mutation, the binding of repressor to O₁ alone reduces transcription by a factor of about 10². Even in the repressed state, each cell has a few molecules of β-galactosidase and galactoside permease, presumably synthesized on the rare occasions when the repressor transiently dissociates from the operators. This basal level of transcription is essential to operon regulation. When cells are provided with lactose, the lac operon is induced. An inducer (signal) molecule binds to a specific site on the Lac repressor, causing a conformational change that results in dissociation of the repressor from the operator. The inducer in the lac operon system is not lactose itself but allolactose, an isomer of lactose (Fig. 28-7). After entry into the E. coli cell (via the few existing molecules of lactose permease), lactose is converted to allolactose by one of the few existing β-galactosidase molecules. Release of the operator by Lac repressor, triggered as the repressor binds to allolactose, allows expression of the lac operon genes and leads to a 10⁴-fold increase in the concentration of β-galactosidase. Several β-galactosides structurally related to allolactose are inducers of the lac operon but are not substrates for β-galactosidase; others are substrates but not inducers. One particularly effective and nonmetabolizable inducer of the lac operon that is often used experimentally is

isopropylthiogalactoside (IPTG). $\text{CHOH CH}_2\text{OH}$ Isopropyl- β -D-thiogalactoside (IPTG) An inducer that cannot be metabolized allows researchers to explore the physiological function of lactose as a carbon source for growth, separate from its function in the regulation of gene expression. In addition to the multitude of operons now known in bacteria, a few polycistronic operons have been found in the cells of lower eukaryotes. In the cells of higher eukaryotes, however, almost all protein-encoding genes are transcribed separately. The mechanisms by which operons are regulated can vary significantly from the simple model presented in Figure 28-8. Even the lac operon is more complex than indicated here, with an activator also contributing to the overall scheme, as we shall see in Section 28.2. Before any further discussion of the layers of regulation of gene expression, however, we examine the critical molecular interactions between DNA-binding proteins (such as repressors and activators) and the DNA sequences to which they bind.

Regulatory Proteins Have Discrete DNA-Binding Domains

Regulatory proteins generally bind to specific DNA sequences. Their affinity for these target sequences is roughly 10^4 to 10^6 times higher than their affinity for any other DNA sequence. Most regulatory proteins have discrete DNA-binding domains containing substructures

(a) Major groove Major groove 28.1 Principles of Gene Regulation 1161 Major groove Major groove Minor groove Minor groove Adenine = Thymine Guanine = Cytosine (b) Major groove C000: 6 < @000 < T0000 000(O000: 000: FIGURE 28-9 Groups in DNA available for protein binding. (a) Shown here are functional groups on all four base pairs that are displayed in the Minor groove C00: 6@@@: @ H-bond donor @ Other H O Methyl group major and minor grooves of DNA (see Fig. 8-13). Hydrogen-bond acceptor and donor atoms are marked by blue and red disks, respectively. Other hydrogen atoms are marked with purple disks, and methyl groups with that interact closely and specifically with the DNA. These binding domains usually include one or more of a relatively small group of recognizable and characteristic structural motifs. To bind specifically to DNA sequences, regulatory proteins must recognize surface features on the DNA. Most of the chemical groups that differ among the four bases and thus permit discrimination between base pairs are hydrogen-bond donor and acceptor groups exposed in the major groove of DNA (Fig. 28-9), and most of the protein-DNA contacts that impart specificity are hydrogen bonds. A notable exception is the nonpolar surface near C-5 of pyrimidines, where thymine is readily distinguished from cytosine by its protruding methyl group. Protein-DNA contacts are also possible in the minor groove of the DNA, but the hydrogen-bonding patterns here generally do not allow ready discrimination between base pairs. Within regulatory proteins, the amino acid side chains most often hydrogen-bonding to bases in the DNA are those of Asn, Gln, Glu, Lys, and Arg residues. Is there a simple recognition code in which a particular amino acid always pairs with a particular base? The two hydrogen bonds that can form between Gln or Asn and the N° and N-7 positions of adenine cannot form with any other base. And an Arg residue can form two hydrogen bonds with N-7 and O° of guanine (Fig. 28-10). Examination of the structure of many DNA-binding proteins, however, has shown that a protein can recognize @ H-bond acceptor Minor groove Minor groove Thymine = Adenine Cytosine = Guanine yellow disks. (b) Recognition patterns for each base pair, from left to right, are summarized at bottom. The much greater variation in the patterns for the major groove gives rise to a much greater discriminatory power in the major groove relative to the minor groove. each base pair in more than

one way, leading to the conclusion that there is no simple amino acid—base code. For some proteins, the Gln-adenine interaction can specify A=T base pairs, but in others a van der Waals pocket for the methyl group of thymine can recognize A=T base pairs. Researchers cannot yet examine the structure of a DNA-binding protein and infer the DNA sequence to which it binds. 1162 Regulation of Gene Expression To interact with bases in the major groove of DNA, a protein requires a relatively small substructure that can stably protrude from the protein surface. The DNA-binding domains of regulatory proteins tend to be small (60 to 90 amino acid residues), and the structural motifs within these domains that are actually in contact with the DNA are smaller still. Many small proteins are unstable because of their limited capacity to form layers of structure to bury hydrophobic groups (p. 116). The DNA-binding motifs provide either a very compact stable structure or a way of allowing a segment of protein to protrude from the protein surface. The DNA-binding sites for regulatory proteins are often inverted repeats of a short DNA sequence (a palindrome) at which multiple (usually two) subunits of a regulatory protein bind cooperatively. The Lac repressor is unusual in that it functions as a tetramer, with two dimers tethered together at the end distant from the DNA-binding sites (Fig. 28-8b). An *E. coli* cell usually contains about 20 tetramers of the Lac repressor. Each of the tethered dimers separately binds to a palindromic operator sequence, in contact with 17 bp of a 22 bp region in the lac operon. And each of the tethered dimers can independently bind to an operator sequence, with one generally binding to O, and the other to O_x or O_g (as in Fig. 28-8b). The symmetry of the O; operator sequence corresponds to the twofold axis of symmetry of two paired Lac repressor subunits. The tetrameric Lac repressor binds to its operator sequences in vivo with an estimated dissociation constant of about 10⁻⁹ M. The repressor discriminates between the operators and other sequences by a factor of about 10⁶, so binding to these few base pairs among the 4.6 million or so of the *E. coli* chromosome is highly specific. Several DNA-binding motifs have been described, but here we focus on two that play prominent roles in the binding of DNA by regulatory proteins: the helix-turn-helix and the zinc finger. We also consider a type of DNA-binding domain—the homeodomain—found in some eukaryotic proteins.

Helix-Turn-Helix This DNA-binding motif is crucial to the interaction of many bacterial regulatory proteins with DNA, and similar motifs occur in some eukaryotic regulatory proteins. The helix-turn-helix motif comprises about 20 amino acids in two short α -helical segments, each seven to nine amino acid residues long, separated by a β turn (Fig. 28-11). This structure generally is not

stable by itself; it is simply the reactive portion of a somewhat larger DNA-binding domain. One of the two α -helical segments is called the recognition helix because it usually contains many of the amino acids that interact with the DNA in a sequence-specific way. This α helix is stacked on other segments of the protein structure so that it protrudes from the protein surface. When bound to DNA, the recognition helix is positioned (a) * _DNA recognition helix *. -Turn DNA-binding domain in tetramer formation FIGURE 28-11 Helix-turn-helix. (PDB ID 2PE5) (a) DNA-binding domain of the Lac repressor bound to DNA (blue and orange). The helix-turn-helix motif is shown in dark blue and purple; the DNA recognition helix is purple. (b) Entire Lac repressor. The DNA-binding domains are light blue, and the α helices involved in tetramer formation are green. The remainder of the protein (shades of red) has the binding sites for allolactose. The allolactose-binding domains are linked to the DNA-binding domains through linker helices (yellow). in or nearly in the major groove. The Lac repressor has this DNA-binding motif (Fig. 28-11). Zinc Finger In a zinc finger, about 30 amino acid residues form an elongated loop held together at the base by a single Zn^{2+} ion, which is coordinated to four of the residues (four Cys, or two Cys and two His). The zinc does not itself interact with DNA; rather, the coordination of zinc with the amino acid residues stabilizes this small structural motif. Several hydrophobic side chains in the core of the structure also lend stability. Figure 28-12 shows the interaction between DNA and three zinc fingers of a single polypeptide from the mouse regulatory protein Zif268. Many eukaryotic DNA-binding proteins contain zinc fingers. The interaction of a single zinc finger with DNA is typically weak, and many DNA-binding proteins, like Zif268, have multiple zinc fingers that substantially enhance binding by interacting simultaneously with the DNA. One DNA-binding protein of the frog *Xenopus* has 37 zinc fingers. There are few known examples of the zinc finger motif in bacterial proteins.

Zinc finger motif —————; Zinc finger,“ motif Zinc finger motif

FIGURE 28-12 Zinc fingers. (PDB ID 1ZAA) Three zinc fingers (shades of red) of the regulatory protein Zif268, complexed with DNA (blue). Each Zn²⁺ coordinates with two His and two Cys residues. The precise manner in which proteins with zinc fingers bind to DNA differs from one protein to the next. Some zinc fingers contain the amino acid residues that are important in sequence discrimination, whereas others seem to bind DNA nonspecifically (the amino acids required for specificity are located elsewhere in the protein). Zinc fingers can also function as RNA-binding motifs—for example, in certain proteins that bind eukaryotic mRNAs and act as translational repressors. We discuss this role later (Section 28.3).

Homeodomain Another type of DNA-binding domain has been identified in some proteins that function as transcriptional regulators, especially during eukaryotic development. This domain of 60 amino acids—called the homeodomain because it was discovered in homeotic genes (genes that regulate the development of body patterns)—is highly conserved and has now been identified in proteins from a wide variety of organisms, including humans (Fig. 28-13). The DNA-binding segment of the domain is related to the helix-turn-helix motif. The DNA sequence that encodes this domain is known as the homeobox.

Regulatory Proteins Also Have Protein-Protein Interaction Domains Regulatory proteins contain domains not only for DNA binding but also for protein-protein interactions—with RNA polymerase, other regulatory proteins, or other subunits of the same regulatory protein. Examples include many eukaryotic transcription factors that function as gene activators, which often bind as dimers to the DNA, through DNA-binding domains that contain zinc fingers. Some structural domains are devoted to the interactions required for dimer formation, which is generally a prerequisite for DNA binding. Like DNA-binding motifs, the structural motifs that mediate protein-protein interactions tend to fall within one of a few common categories.

Two important examples

28.1 Principles of Gene Regulation 1163

Recognition helix Helix .

FIGURE 28-13 Homeodomains. (PDB ID 1FJL) Shown here are two homeodomains bound to DNA. In each homeodomain, one of the α helices (purple), layered on two others (dark blue and gray), can be seen protruding into the major groove. This is only a small part of a larger regulatory protein from a class

called Pax, active in the regulation of development in fruit flies (see Section 28.3). are the leucine zipper and the basic helix-loop-helix. Structural motifs such as these are the basis for classifying some regulatory proteins into structural families.

Leucine Zipper This motif is an amphipathic α helix with a series of hydrophobic amino acid residues concentrated on one side (Fig. 28-14), with the hydrophobic surface forming the area of contact between the two polypeptides of a dimer. A striking feature of these α helices is the occurrence of Leu residues at every seventh position, forming a straight line along the hydrophobic surface. Although researchers initially thought the Leu residues interdigitated (hence the name “zipper”), we now know that they line up side by side as the interacting α helices coil around each other (forming a coiled coil; Fig. 28-14b). Regulatory proteins with leucine zippers often have a separate DNA-binding domain with a high concentration of basic (Lys or Arg) residues that can interact with the negatively charged phosphates of the DNA backbone. Leucine zippers have been found in many eukaryotic and a few bacterial proteins.

Basic Helix-Loop-Helix Another common structural motif occurs in some eukaryotic regulatory proteins implicated in the control of gene expression during the development of multicellular organisms. These proteins share a conserved region of about 50 amino acid residues important in both DNA binding and protein dimerization. This region can form two short amphipathic α helices linked by a loop of variable length, the helix-loop-helix (distinct

target site. The protein is dimeric; one subunit is colored. The
recognition helix (pink) is linked via the loop to the dimer-forming
helix (light blue), which merges with the carboxyl-terminal end of
the subunit. Interaction of the carboxyl-terminal helices of the two
subunits describes a coiled coil very similar to that of a leucine
zipper (see Fig. 28-14b), but with only one pair of interacting Leu
residues (red side chains at the right) in this example. The overall
structure is sometimes called a helix-loop-helix/leucine zipper
motif. T ces (gray), derived from different subunits of Zipper i the
dimeric protein, are shown. The two helices region wrap around
each other in a gently coiled coil. The interacting Leu side chains
and the conserved residues in the DNA-binding region are colored
to correspond to the sequence in (a). Protein-Protein Interactions in
Eukaryotic Regulatory Proteins In eukaryotes most genes are
regulated by activators, and most genes are monocistronic. If a
different activator were required for each gene, the number of
activators (and genes encoding them) would need to be equivalent
to the number of regulated genes. However, in yeast about 300

transcription factors (many of them activators) are responsible for the regulation of many thousands of yeast genes. Many of the transcription factors regulate the induction of multiple genes, but most genes are subject to regulation by multiple transcription factors. Appropriate regulation of different genes is accomplished by utilizing different combinations of a limited repertoire of transcription factors at each gene, a phenomenon referred to as combinatorial control. Combinatorial control is accomplished in part by mixing and matching the variants within a regulatory protein family to form a series of different active protein dimers. Several families of eukaryotic transcription factors have been defined based on close structural similarities. Within each family, dimers can sometimes form between two identical proteins (a homodimer) or between two different members of the family (a heterodimer). A hypothetical family of four different leucine-zipper proteins could thus form up to 10 different dimeric species. In many cases, the different combinations have distinct regulatory and functional properties and function in the regulation of different genes. As we shall see, multiple regulatory proteins of this kind function in the regulation

of most eukaryotic genes, contributing further to combinatorial control. In addition to having structural domains devoted to DNA binding and dimerization that direct a particular protein dimer to a particular gene, many regulatory proteins have domains that interact with RNA polymerase, with unrelated regulatory proteins, or with both. At least three types of additional domains for protein-protein interaction have been characterized (primarily in eukaryotes): glutamine-rich, proline-rich, and acidic domains, the names reflecting the amino acid residues that are especially abundant. Protein-DNA binding interactions are the basis of the intricate regulatory circuits fundamental to gene function. We now turn to a closer examination of these gene regulatory schemes, first in bacterial, then in eukaryotic systems.

SUMMARY

28.1 Principles of Gene Regulation > The expression of genes is regulated by processes that affect the rates at which gene products are synthesized and degraded. Much of this regulation occurs at the level of transcription initiation, mediated by regulatory proteins that either repress transcription (negative regulation) or activate transcription (positive regulation) at specific promoters. > In bacteria, genes that encode products with interdependent functions are often clustered in an operon, a single transcriptional unit. Transcription of the genes is generally blocked by binding of a specific repressor protein at a DNA site called an operator. Dissociation of the repressor from the operator is mediated by a specific small molecule, an inducer. These principles were first elucidated in studies of the lactose (lac) operon. The Lac repressor dissociates from the lac operator when the repressor binds to its inducer, allolactose. > Regulatory proteins are DNA-binding proteins that recognize specific DNA sequences; most have distinct DNA-binding domains. Within these domains, common structural motifs that bind DNA are the helix-turn-helix, zinc finger, and homeodomain. > Regulatory proteins also contain domains for protein-protein interactions, including the leucine zipper and helix-loop-helix, which are involved in dimerization, and other motifs involved in activation of transcription. Mixing and matching of protein family variants in dimeric transcription factors provides for more efficient and responsive regulation through combinatorial control.

28.2 Regulation of Gene Expression in Bacteria 1165 **28.2 Regulation of Gene Expression in Bacteria** As in many other areas of

biochemical investigation, the study of the regulation of gene expression advanced earlier and faster in bacteria than in other experimental organisms. The examples of bacterial gene regulation presented here are chosen from among scores of wellstudied systems, partly for their historical significance, but primarily because they provide a good overview of the range of regulatory mechanisms in bacteria. Many of the principles of bacterial gene regulation are also relevant to understanding gene expression in eukaryotic cells. We begin by examining the lactose and tryptophan operons; each system has regulatory proteins, but the overall mechanisms of regulation are very different. This is followed by a short discussion of the SOS response in *E. coli*, illustrating how genes scattered throughout the genome can be coordinately regulated. We then describe two bacterial systems of quite different types, illustrating the diversity of gene regulatory mechanisms: regulation of ribosomal protein synthesis at the level of translation, with many of the regulatory proteins binding to RNA (rather than DNA), and regulation of the process of “phase variation” in *Salmonella*, which results from genetic recombination. Finally, we examine some additional examples of posttranscriptional regulation in which the RNA modulates its own function.

The *Jac* Operon Undergoes Positive Regulation

The operator-repressor-inducer interactions described earlier for the *lac* operon (Fig. 28-8) provide an intuitively satisfying model for an on/off switch in the regulation of gene expression. In truth, operon regulation is rarely so simple. A bacterium's environment is too complex for its genes to be controlled by one signal. Other factors besides lactose affect the expression of the *lac* genes, such as the availability of glucose. Glucose, metabolized directly by glycolysis, is the preferred energy source in *E. coli*. Other sugars can serve as the main or sole nutrient, but extra enzymatic steps are required to prepare them for entry into glycolysis, necessitating the synthesis of additional enzymes. Clearly, expressing the genes for proteins that metabolize sugars such as lactose or arabinose is wasteful when glucose is abundant. What happens to the expression of the *Jac* operon when both glucose and lactose are present? A regulatory mechanism known as catabolite repression restricts expression of the genes required for catabolism of lactose, arabinose, and other sugars in the presence of glucose, even when these secondary sugars are also present. The effect of glucose is mediated by cAMP, as a

coactivator, and an activator protein known as cAMP receptor protein, or CRP (the protein is sometimes

1166 Regulation of Gene Expression cAMP ~} RNA polymerase ~~ contacts

FIGURE 28-16 CRP homodimer with bound cAMP. (PDB ID 1RUN) Note the bending of the DNA around the protein. The region that interacts with RNA polymerase is indicated. called CAP, for catabolite gene activator protein). CRP is a homodimer (subunit M, 22,000) with binding sites for DNA and cAMP. Binding is mediated by a helix-turnhelix motif in the protein's DNA-binding domain (Fig. 28-16). When glucose is absent, CRP-cAMP binds to a site near the lac promoter (Fig. 28-17) and stimulates RNA transcription 50-fold. CRP-cAMP is therefore a positive regulatory element responsive to glucose levels, whereas the Lac repressor is a negative regulatory element responsive to lactose. The two act in concert. CRP-cAMP has little effect on the lac operon when the Lac repressor is blocking transcription, and dissociation of the repressor from the lac operator has little effect on transcription of the lac operon unless CRP-cAMP is present to facilitate transcription; when CRP is not bound, the wild-type lac promoter is a relatively weak promoter (Fig. 28-17a, c). The open complex of RNA polymerase and the promoter (see Fig. 26-6) does not form readily unless CRP-cAMP is present. CRP interacts directly with RNA polymerase (at the region shown in Fig. 28-16) through the polymerases α subunit. The effect of glucose on CRP is mediated by the cAMP interaction (Fig. 28-17). CRP binds to DNA most avidly when cAMP concentrations are high. In the presence of glucose, the synthesis of cAMP is inhibited and efflux of cAMP from the cell is stimulated. As [cAMP] declines, CRP binding to DNA declines, thereby decreasing the expression of the lac operon. Strong induction of the lac operon therefore requires both lactose (to inactivate the lac repressor) and a lowered concentration of glucose (to trigger an increase in [cAMP] and increased binding of cAMP to CRP). CRP and cAMP are involved in the coordinated regulation of many operons, primarily those that encode enzymes for the metabolism of secondary sugars such as lactose and arabinose. A network of operons with a

of the lac operon by CRP. The binding site for CRP-cAMP is near the promoter. The combined effects of glucose and lactose availability on lac operon expression are shown. When lactose is absent, the repressor binds to the operator and prevents transcription of the lac genes. It does not matter whether glucose is (a) present or (b) absent. (c) If lactose is present, the repressor dissociates from the operator. However, if glucose is also available, low cAMP levels prevent CRP-cAMP formation and DNA binding. RNA polymerase may occasionally bind and initiate transcription, resulting in a very low level of lac gene + ranscription. (d) When lactose is present and glucose levels are low, CAMP evels rise. The CRP-cAMP complex forms and facilitates robust binding of re) A polymerase to the lac promoter and high levels of transcription. common regulator is called a regulon. This arrangement, which allows for coordinated shifts in cellular functions that can require the action of hundreds of genes, is a major theme in the regulated expression of dispersed networks of genes in eukaryotes. Other bacterial regulons include the heat shock gene system that

Trp repressor Attenuator Leader (trpL) 28.2 Regulation of Gene Expression in Bacteria 1167 FIGURE 28-18 The trp operon. This operon is regulated by two mechanisms: when tryptophan levels are high, (1) the repressor (upper left) binds to its operator and (2) transcription of trp mRNA is attenuated (see Fig. 28-19). The biosynthesis of tryptophan by the enzymes encoded in the trp operon is diagrammed at the bottom (see also Fig. 22-19).

Many Genes for Amino Acid Biosynthetic Enzymes Are Regulated by Transcription Attenuation The 20 common amino acids are required in large amounts for protein synthesis, and *Æ. coli* can synthesize all of them. The genes for the enzymes needed to synthesize a given amino acid are generally clustered in an operon and are expressed whenever existing supplies of that amino acid are inadequate for cellular requirements. When the amino acid is abundant, the biosynthetic enzymes are not needed and the operon is repressed. The *Æ. coli* tryptophan (trp) operon (Fig. 28-18) includes five genes for the enzymes required to convert chorismate to tryptophan. Note that two of the enzymes catalyze more than one step in the pathway. The mRNA from the trp operon has a half-life of only about 3 min, allowing the cell to respond rapidly to changing needs for this amino acid. The Trp repressor is a homodimer. When tryptophan is abundant, it binds to the Trp repressor, causing a conformational change that permits the repressor to bind to the trp operator and inhibit expression of the trp operon. The trp operator site overlaps the promoter, so binding of the repressor blocks binding of RNA polymerase. Once again, this simple on/off circuit

mediated by a repressor is not the entire regulatory story. Different cellular concentrations of tryptophan can vary the rate of synthesis of the biosynthetic enzymes over a 700-fold range. Once repression is lifted and transcription begins, the rate of transcription is fine-tuned to cellular tryptophan requirements by a second regulatory process, called transcription attenuation, in which transcription is initiated normally but is abruptly halted before the operon genes are transcribed. The frequency with which transcription is attenuated is regulated by the availability of tryptophan and relies on the very close coupling of transcription and translation in bacteria. The trp operon attenuation mechanism uses signals encoded in four sequences within a 162 nucleotide leader region at the 5' end of the mRNA, preceding the initiation codon of the first gene (Fig. 28-19a). Within the leader lies a region known as the attenuator, made up of sequences 3 and 4. These sequences base-pair to form a G = C-rich stem-and-loop structure closely followed by a series of U residues. The attenuator structure acts as a transcription terminator (Fig. 28-19b). Sequence 2 is an alternative complement for sequence 3 (Fig. 28-19c). If sequences 2 and 3 base-pair, the attenuator structure cannot form and transcription continues into the trp biosynthetic genes; the loop formed by the pairing of sequences 2 and 3 does not obstruct transcription.

When tryptophan levels are high, the ribosome quickly translates sequence 1 (open reading frame encoding leader peptide) and blocks sequence 2 before sequence 3 is transcribed. Continued transcription leads to attenuation at the terminator-like attenuator structure formed by sequences 3 and 4. Attenuator structure DNA trpL Incomplete MK4yq leader peptide p When tryptophan levels are low, the ribosome pauses at the Trp codons in sequence 1. Formation of the paired structure between sequences 2 and 3 prevents attenuation, because sequence 3 is no longer available to form the attenuator structure with sequence 4. The 2:3 structure, unlike the 3:4 attenuator, does not prevent transcription. (b) FIGURE 28-19 Transcriptional attenuation in the trp operon. Transcription is initiated at the beginning of the 162 nucleotide mRNA leader encoded by a DNA region called trpL (see Fig. 28-18). A regulatory mechanism determines whether transcription is attenuated at the end of the leader or continues into the structural genes. (a) The trp mRNA leader (trpL). The attenuation mechanism in the trp operon involves sequences 1 to 4 (highlighted). (b) Sequence 1 encodes a small peptide, the leader peptide, containing two Trp residues (W); it is translated immediately after transcription begins. Sequences 2 and 3 are complementary, as are sequences trp-regulated genes Bs F / GUACCACUUAUGUGACGGGCAAMBUCCUUCACECasUGGUS oS (stop)-Ser —Thr—Arg—Trp —Trp — 162 Met - Gln -Thr —> TrpE polypeptide End of leader region (trpL) RNA polymerase 3:4 Pair (attenuator) RNA ENO 2:3 Pair (c) 3 and 4. The attenuator structure forms by the pairing of sequences 3 and 4 (top). Its structure and function are similar to those of a transcription terminator (see Fig. 26-7a). Pairing of sequences 2 and 3 (bottom) prevents the attenuator structure from forming. Note that the leader peptide has no other cellular function. Translation of its open reading frame has a purely regulatory role that determines which complementary sequences (2 and 3 or 3 and 4) are paired. (c) Base-pairing schemes for the complementary regions of the trp mRNA leader.

Regulatory sequence 1 is crucial for a tryptophan-sensitive mechanism that determines whether sequence 3 pairs with sequence 2 (allowing transcription to continue) or with sequence 4 (attenuating transcription). Formation of the attenuator stem-and-loop structure depends on events that occur during translation of regulatory sequence 1, which encodes a leader peptide (so called because it is encoded by the leader region of the mRNA) of 14 amino acids, two of which are Trp residues. The leader peptide has no other known cellular function; its synthesis is simply an operon regulatory device. This peptide is translated immediately after it is transcribed, by a ribosome that follows closely behind RNA polymerase as transcription proceeds. When tryptophan concentrations are high, concentrations of charged tryptophan tRNA (Trp-tRNATM) are also high. This allows translation to proceed rapidly past the two Trp codons of sequence 1 and into sequence 2, before sequence 3 is synthesized by RNA polymerase. In this situation, sequence 2 is covered by the ribosome and unavailable for pairing to sequence 3 when sequence 3 is synthesized; the attenuator structure (sequences 3 and 4) forms and transcription halts (Fig. 28-19b, top). When tryptophan concentrations are low, however, the ribosome stalls at the two Trp codons in sequence 1 because charged tRNATM is less available. Sequence 2 remains free while sequence 3 is synthesized, allowing these two sequences to base-pair and permitting transcription to proceed (Fig. 28-19b, bottom). In this way, the proportion of transcripts that are attenuated declines as tryptophan concentration declines.

E. coli chromosome polB dinB uvrB uvrA sulA RecA protein (1) Damage to (SN DNA produces N single-strand gap LexA repressor lexA recA activated proteolysis C9 eca binds to Co single-stranded DNA umuC,D 28.2 Regulation of Gene Expression in Bacteria 1169 Many other amino acid biosynthetic operons use a similar attenuation strategy to fine-tune biosynthetic enzymes to meet the prevailing cellular requirements. The 15 amino acid leader peptide produced by the phe operon contains seven Phe residues. The leu operon leader peptide has four contiguous Leu residues. The leader peptide for the his operon contains seven contiguous His residues. In fact, in the his operon and a number of others, attenuation is sufficiently sensitive to be the only regulatory mechanism. Induction of the SOS Response Requires Destruction of Repressor Proteins Extensive DNA

damage in the bacterial chromosome triggers the induction of many distantly located genes. This response, called the SOS response (p. 1035), provides another good example of coordinated gene regulation. Many of the induced genes are involved in DNA repair (see Table 25-6). The key regulatory proteins are the RecA protein and the LexA repressor. The LexA repressor (M, 22,700) inhibits transcription of all the SOS genes (Fig. 28-20), and induction of the SOS response requires removal of LexA. This is not a simple dissociation from DNA in response to binding of a small molecule, as in the regulation of the lac operon described above. Instead, the LexA repressor is inactivated when it catalyzes its own cleavage at a specific Ala—Gly peptide bond, producing two roughly equal protein fragments. At physiological pH, this autocleavage reaction requires the RecA protein. RecA is not a

FIGURE 28-20 SOS response in *E. coli*. See Table 25-6 for the functions of many of these proteins. The LexA protein is the repressor in this system, which has an operator site (red) near each gene. Because the *recA* gene is not entirely repressed by the LexA repressor, the normal cell contains about 1,000 RecA monomers. @ When DNA is extensively damaged (such as by UV light), DNA replication is halted and the number of single-strand gaps in the DNA increases. @ RecA protein binds to this damaged, single-stranded DNA, activating the protein's coprotease activity. @ While bound to DNA, the RecA protein facilitates cleavage and inactivation of the LexA repressor. When the repressor is inactivated, the SOS genes, including *recA*, are induced; RecA levels increase 50- to 100-fold.

1170 Regulation of Gene Expression

protease in the classical sense, but its interaction with LexA facilitates the repressor's self-cleavage reaction. This function of RecA is sometimes called a co-protease activity. The RecA protein provides the functional link between the biological signal (DNA damage) and induction of the SOS genes. Heavy DNA damage leads to numerous single-strand gaps in the DNA, and only RecA that is bound to single-stranded DNA can facilitate cleavage of the LexA repressor (Fig. 28-20, bottom). Binding of RecA at the gaps eventually activates its coprotease activity, leading to cleavage of the LexA repressor and SOS induction. During induction of the SOS response in a severely damaged cell, RecA also cleaves and thus inactivates the repressors that otherwise allow propagation of certain viruses in a dormant lysogenic state within the bacterial host. This provides a remarkable illustration of evolutionary adaptation. These repressors, like LexA, also undergo self-cleavage at a specific Ala—Gly peptide bond, so induction of the SOS response permits replication of the virus and lysis of the cell, releasing new viral particles. Thus the bacteriophage can make a hasty exit from a compromised bacterial host cell.

Synthesis of Ribosomal Proteins Is Coordinated with rRNA Synthesis

In bacteria, an increased cellular demand for protein synthesis is met by increasing the number of ribosomes rather than altering the activity of individual ribosomes. In general, the number of ribosomes increases as the cellular growth rate increases. At high growth rates, ribosomes make up approximately 45% of the cell's dry weight. The proportion of cellular resources devoted to making ribosomes is so large, and the function of ribosomes so important, that cells must coordinate the synthesis of the ribosomal components: the ribosomal proteins (r-proteins) and RNAs (rRNAs). This regulation is distinct from the mechanisms described so far, because it occurs largely at the level of translation. The 52 genes that encode the r-proteins occur in at least 20 operons, each with 1 to 11 genes. Some of these operons also contain the genes for the subunits of DNA primase (see Fig. 25-12), RNA polymerase (see Fig. 26-4), and protein synthesis elongation factors (see Fig. 27-29)—revealing the close coupling of replication, transcription, and protein synthesis during cell growth. The r-protein operons are regulated primarily through a translational feedback mechanism. One r-protein encoded by each

operon also functions as a translational repressor, which binds to the mRNA transcribed from that operon and blocks translation of all the genes the messenger encodes (Fig. 28-21). In general, the r-protein that plays the role of repressor also binds directly to an rRNA. Each translational repressor r-protein binds with higher affinity to the appropriate rRNA than to its mRNA, so the mRNA is bound and EN: a@ operon al S10 operon spc operon FIGURE 28-21 Translational feedback in some ribosomal protein operons. The r-proteins that act as translational repressors are shaded light red. Each translational repressor blocks the translation of all genes in that operon by binding to the indicated site on the mRNA. Genes that encode subunits of RNA polymerase are shown in purple; genes that encode elongation factors are blue. The r-proteins of the large (50S) ribosomal subunit are designated L1 to L34; those of the small (30S) subunit, S1 to S21. translation repressed only when the level of the r-protein exceeds that of the rRNA. This ensures that translation of the mRNAs encoding r-proteins is repressed only when synthesis of these r-proteins exceeds that needed to make functional ribosomes. In this way, the rate of r-protein synthesis is kept in balance with rRNA availability. The mRNA-binding site for the translational repressor is near the translational start site of one of the genes in the operon, usually the first gene (Fig. 28-21). In other operons this would affect only that one gene, because in bacterial polycistronic mRNAs most genes have independent translation signals. In the r-protein operons, however, the translation of one gene depends on the translation of all the others. The mechanism of this translational coupling is not yet understood in detail. However, in some cases the translation of multiple genes seems to be blocked by folding of the mRNA into an elaborate three-dimensional structure that is stabilized both by internal base-pairing (as in Fig. 8-24) and by binding of the translational repressor protein. When the translational repressor is absent, ribosome binding and translation of one or more of the genes disrupts the folded structure of the mRNA and allows all the genes to be translated.

Because the synthesis of r-proteins is coordinated with the available rRNA, the regulation of ribosome production reflects the regulation of rRNA synthesis. In *E. coli*, rRNA synthesis from the seven rRNA operons responds to cellular growth rate and to changes in the availability of crucial nutrients, particularly amino acids. The regulation coordinated with amino acid concentrations is known as the stringent response (Fig. 28-22). When amino acid concentrations are low, rRNA synthesis is halted. Amino acid starvation leads to the binding of uncharged tRNAs to the ribosomal A site; this triggers a sequence of events that begins with the binding of an enzyme called stringent factor (RelA protein) to the ribosome. When bound to the ribosome, stringent factor catalyzes formation of the unusual nucleotide guanosine tetraphosphate (ppGpp; see Fig. 8-39); it adds pyrophosphate to the 3' position of GTP, in the reaction $\text{GTP} + \text{ATP} \rightarrow \text{pppGpp} + \text{AMP}$ then a phosphohydrolase cleaves off one phosphate to form ppGpp. The abrupt rise in ppGpp level in response to amino acid starvation results in a great reduction in rRNA synthesis, mediated at least in part by the binding of ppGpp to RNA polymerase. The nucleotide ppGpp, along with cAMP, belongs to a class of modified nucleotides that act as cellular second Growing polypeptide Stringent factor (RelA protein) 3' Gpp + AMP GTP + ATP eae RP 4 ana & polymerase

FIGURE 28-22 Stringent response in *E. coli*. This response to amino acid starvation is triggered by binding of an uncharged tRNA in the ribosomal A site. A protein called stringent factor binds to the ribosome and catalyzes the synthesis of pppGpp, which is converted by a phosphohydrolase to ppGpp. The signal ppGpp reduces transcription of some genes and increases that of others, in part by binding to the B subunit of RNA polymerase and altering the enzyme's promoter specificity. Synthesis of rRNA is reduced when ppGpp levels increase.

28.2 Regulation of Gene Expression in Bacteria

1171 messengers (p. 308). In *E. coli*, these two nucleotides serve as starvation signals; they cause large changes in cellular metabolism by increasing or decreasing the transcription of hundreds of genes. In eukaryotic cells, similar nucleotide second messengers also have multiple regulatory functions. The coordination of cellular metabolism with cell growth is highly complex, and further regulatory mechanisms undoubtedly remain to be discovered.

The Function of Some mRNAs Is Regulated by Small

RNAs in Cis or in Trans As described throughout this chapter, proteins play an important and well-documented role in regulating gene expression. But RNA also has a crucial role—one that is becoming better recognized as more examples of regulatory RNAs are discovered. Once an mRNA is synthesized, its functions can be controlled by RNA-binding proteins, as seen for the *r*-protein operons just described, or by an RNA. A separate RNA molecule may bind to the mRNA “in trans” and affect its activity. Alternatively, a portion of the mRNA itself may regulate its own function. When part of a molecule affects the function of another part of the same molecule, it is said to act “in cis.” A well-characterized example of RNA regulation in trans is seen in the regulation of the mRNA of the gene *rpoS* (RNA polymerase sigma factor), which encodes σ^{70} , one of the seven *E. coli* sigma factors (see Table 26-1). The cell uses this specificity factor in certain stress situations, such as when it enters the stationary phase (a state of no growth, necessitated by lack of nutrients) and σ^{70} is needed to transcribe large numbers of stress response genes. The *rpoS* mRNA is present at low levels under most conditions but is not translated, because a large hairpin structure upstream of the coding region inhibits ribosome binding (Fig. 28-23). Under certain stress conditions, one or both of two small specialfunction RNAs, DsrA (downstream region A) and RprA (Rpos regulator RNA A), are induced. Both can pair with one strand of the hairpin in the *rpoS* mRNA, disrupting the hairpin and thus allowing translation of *rpoS*. Another small RNA, OxyS (oxidative stress gene S), is induced under conditions of oxidative stress and inhibits the translation of *rpoS*, probably by pairing with and blocking the ribosome-binding site on the mRNA. OxyS is expressed as part of a system that responds to a different type of stress (oxidative damage) than does *rpoS*, and its task is to prevent expression of unneeded repair pathways. DsrA, RprA, and OxyS are all relatively small bacterial RNA molecules (less than 300 nucleotides), designated sRNAs (s for small; there are of course other “small” RNAs with other designations in eukaryotes). All require for their function a protein called Hfq, an RNA chaperone that facilitates RNA-RNA pairing. The known bacterial genes regulated in this way are few in number, just a few dozen in a typical bacterial species. However, these examples provide

1172 Regulation of Gene Expression (a) *rpoS* mRNA Ribosomebinding site DsrA 3' 5' Ribosomebinding site FIGURE 28-23 Regulation of bacterial mRNA function in trans by sRNAs. Several sRNAs (small RNAs)—DsrA, RprA, and OxyS—are involved in regulation of the *rpoS* gene. All require the protein Hfq, an RNA chaperone that facilitates RNA-RNA pairing. Hfq has a toroid structure, with a pore in the center. (a) DsrA promotes translation by pairing with one strand of a stem-loop structure that otherwise blocks the ribosome-binding site. RprA (not shown) acts in a similar way. (b) OxyS blocks translation by pairing with the ribosome-binding site. good model systems for understanding patterns present in the more complex and numerous examples of RNA-mediated regulation in eukaryotes. Regulation in cis involves a class of RNA structures known as riboswitches. As described in Box 26-3, aptamers are RNA molecules, generated in vitro, that are capable of specific binding to a particular ligand. As one might expect, such ligand-binding RNA domains are also present in nature—in riboswitches—in a significant number of bacterial mRNAs (and even in some eukaryotic mRNAs). These natural aptamers are structured domains found in untranslated regions at the 5' ends of certain bacterial mRNAs. Binding of an mRNA's riboswitch to its appropriate ligand results in a conformational change in the mRNA, and transcription is inhibited by stabilization of a premature transcription termination structure, or translation is inhibited (in cis) by occlusion of the ribosome-binding site (Fig. 28-24). In most cases, the riboswitch acts in a kind of feedback Aptamer Ribosomebinding site 5' Stabilization of a transcription terminator poly(U) structure aborts terminator transcription. (a) 3' Blockage of the ribosome-binding site blocks translation. (b) 3' 5' (c) Regulation of intron splicing in fungal and plant introns. AG 3' 5' GUACGG 3' splice site 5' splice site FIGURE 28-24 Regulation of bacterial mRNA function in cis by riboswitches. The known modes of action are illustrated by several different riboswitches based on a widespread natural aptamer that binds thiamine pyrophosphate. TPP binding to the aptamer leads to a conformational change that produces the varied results illustrated in parts (a), (b), and (c) in the different systems in which the aptamer is utilized. loop. Most genes regulated in this way are involved in the synthesis or transport of the ligand that is bound by the riboswitch; thus, when the ligand is present in

high concentrations, the riboswitch inhibits expression of the genes needed to replenish this ligand. Each riboswitch binds only one ligand. Distinct riboswitches have been detected that respond to more than a dozen different ligands, including thiamine pyrophosphate (TPP, vitamin B₁), cobalamin (vitamin B₁₂), flavin mononucleotide, lysine, S-adenosylmethionine (adoMet), purines, N-acetylglucosamine 6-phosphate, and glycine. It is likely that many more remain to be discovered. The riboswitch that responds to TPP seems to be the most widespread; it is found in many bacteria, fungi, and some plants. The bacterial TPP riboswitch inhibits translation in some species and induces premature transcription termination in others (Fig. 28-24). The eukaryotic TPP riboswitch is found in the introns of certain genes and modulates the alternative splicing of those genes (see Fig. 26-21). It is not yet clear how common riboswitches are. However, estimates suggest that more than 4% of the genes of *Bacillus subtilis* are regulated by riboswitches.

As riboswitches become better understood, researchers are finding medical applications. For example, most of the riboswitches described to date, including the one that responds to adoMet, have been found only in bacteria. A drug that bound to and activated the adoMet riboswitch would shut down the genes encoding the enzymes that synthesize and transport adoMet, effectively starving the bacterial cells of this essential cofactor. Drugs of this type are being sought for use as a new class of antibiotics. E The pace of discovery of functional RNAs shows no signs of abatement and continues to enrich the hypothesis that RNA played a special role in the evolution of life (Chapter 26). The sRNAs and riboswitches, like ribozymes and ribosomes, may be vestiges of an RNA world obscured by time but persisting as a rich array of biological devices still functioning in the extant biosphere. The laboratory selection of aptamers and ribozymes with novel ligand-binding and enzymatic functions (see Box 26-3) tells us that the RNA-based activities necessary for a viable RNA world are possible. Discovery of many of the same RNA functions in living organisms tells us that key components for RNA-based metabolism do exist. For example, the natural aptamers of riboswitches may be derived from RNAs that, billions of years ago, bound to cofactors needed to promote the enzymatic processes required for metabolism in the RNA world.

Some Genes Are Regulated by Genetic Recombination We turn now to another mode of bacterial gene regulation, at the level of DNA rearrangement—recombination. *Salmonella typhimurium*, which inhabits the mammalian intestine, moves by rotating the flagella on its cell surface (Fig. 28-25). The many copies of the protein Inverted repeat (hix) 28.2 Regulation of Gene Expression in Bacteria 1173

FIGURE 28-25 *Salmonella typhimurium*, with flagella evident. flagellin (M, 53,000) that make up the flagella are prominent targets of mammalian immune systems. But *Salmonella* cells have a mechanism that evades the immune response: they switch between two distinct flagellin proteins (FliJ and FliC) roughly once every 1,000 generations, using a process called phase variation. The switch is accomplished by periodic inversion of a segment of DNA containing the promoter for a flagellin gene. The inversion is a site-specific recombination reaction (see Fig. 25-37) mediated by the Hin recombinase at specific 14 bp sequences (hix sequences) at either end of the DNA segment. When the DNA segment is in one

orientation, the gene for FljB flagellin and the gene encoding a repressor (FljA) are expressed (Fig. 28-26a); the repressor shuts down expression of the gene for FliC flagellin. When the DNA segment is inverted (Fig. 28-26b), the fljA and fljB genes are no longer transcribed, and the flzC gene is induced as the repressor becomes depleted. The Hin recombinase, encoded Promoter for FljB Promoter and repressor for FliC DNA al hin mRNA fljB and fljA mRNA x Hin recombinase FljB FljA C) flagellin protein (a) (repressor) Transposed segment ~— a hin mRNA fliC mRNA (b) Hin recombinase FliC flagellin

FIGURE 28-26 Regulation of flagellin genes in Salmonella: phase variation. The products of genes fliC and fljB are different flagellins. The hin gene encodes the recombinase that catalyzes inversion of the DNA segment containing the fljB promoter and the hin gene. The recombination sites (inverted repeats) are called hix (yellow). (a) In one orientation, fljB is expressed along with a repressor protein (product of the fljA gene) that represses transcription of the fliC gene. (b) In the opposite orientation, only the fliC gene is expressed; the fljA and fljB genes cannot be transcribed. The interconversion between these two states, known as phase variation, also requires two other nonspecific DNA-binding proteins (not shown), HU and FIS.

Examples of Gene Regulation by Recombination

System	recombination site	recombination Function	Phase variation
(Salmonella)	Hin/hix	Site-specific	Alternative expression of two flagellin genes allows evasion of host immune response.
Host range (bacteriophage λ)	Gin/gix	Site-specific	Alternative expression of two Mating-type switch (yeast) HO endonuclease, RAD52 protein, other proteins/MAT Antigenic variation Varies (trypanosomes)* sets of tail fiber genes affects host range.

Alternative expression of two mating types of yeast, a and α , creates cells of different mating types that can mate and undergo meiosis.

Nonreciprocal gene conversion* Successive expression of different genes encoding the variable surface glycoproteins (VSGs) allows evasion of host immune response. Nonreciprocal gene conversion*

*In nonreciprocal gene conversion (a class of recombination events not discussed in Chapter 25), genetic information is moved from one part of the genome (where it is silent) to another (where it is expressed). The reaction is similar to replicative transposition (see Fig. 25-41). Trypanosomes cause African sleeping sickness and other diseases (see Box 6-3). The outer surface of a trypanosome is made up of multiple copies of a single VSG, the major surface antigen. A cell can change surface antigens to more than 100 different forms, precluding an effective defense by the host immune system. by the *hin* gene in the DNA segment that undergoes inversion, is expressed when the DNA segment is in either orientation, so the cell can always switch from one state to the other. This type of regulatory mechanism has the advantage of being absolute: gene expression is impossible when the gene is physically separated from its promoter (note the position of the *fljB* promoter in Fig. 28-26b). An absolute on/off switch may be important in this system (even though it affects only one of the two flagellin genes) because a flagellum with just one copy of the wrong flagellin might be vulnerable to host antibodies against that protein. The *Salmonella* system is by no means unique. Similar regulatory systems occur in some other bacteria and in some bacteriophages, and recombination systems with similar functions have been found in eukaryotes (Table 28-1). Gene regulation by DNA rearrangements that move genes and/or promoters is particularly common in pathogens that benefit by changing their host range or by changing

their surface proteins, thereby staying ahead of host immune systems. SUMMARY 28.2 Regulation of Gene Expression in Bacteria

- > In addition to repression by the Lac repressor, the *E. coli* lac operon undergoes positive regulation by the cAMP receptor protein (CRP). When [glucose] is low, [cAMP] is high and CRP-cAMP binds to a specific site on the DNA, stimulating transcription of the lac operon and production of lactose-metabolizing enzymes. The presence of glucose depresses [cAMP], decreasing expression of lac and other genes involved in metabolism of secondary sugars. A group of coordinately regulated operons is referred to as a regulon.
- > Operons that produce the enzymes of amino acid synthesis have a regulatory circuit called attenuation, which uses a transcription termination site (the attenuator) in the mRNA. Formation of the attenuator is modulated by a mechanism that couples transcription and translation while responding to small changes in amino acid concentration.
- > In the SOS system, multiple unlinked genes repressed by a single repressor are induced simultaneously when DNA damage triggers RecA protein—facilitated autocatalytic proteolysis of the repressor.
- > In the synthesis of ribosomal proteins, one protein in each r-protein operon acts as a translational repressor. The mRNA is bound by the repressor, and translation is blocked only when the r-protein is present in excess of available rRNA.
- > Posttranscriptional regulation of some mRNAs is mediated by sRNAs that act in trans or by riboswitches, part of the mRNA structure itself, that act in cis.
- > Some genes are regulated by genetic recombination processes that move promoters relative to the genes being regulated. Regulation can also take place at the level of translation.

28.3 Regulation of Gene Expression in Eukaryotes

Initiation of transcription is a crucial regulation point for gene expression in all organisms. Although eukaryotes and bacteria use some of the same regulatory mechanisms, the regulation of transcription in the two systems is fundamentally different. We can define a transcriptional ground state as the inherent activity of promoters and transcriptional machinery *in vivo* in the absence of regulatory sequences. In bacteria, RNA polymerase generally has access to every promoter and can bind and initiate transcription at some level of efficiency in the absence of activators or repressors; the transcriptional ground state is therefore nonrestrictive. In eukaryotes, however, strong promoters are generally inactive *in vivo* in the absence of regulatory proteins; that is, the transcriptional ground state is restrictive. This fundamental difference gives rise to at least four important features that distinguish the regulation of gene expression in eukaryotes from that in bacteria. First, access to eukaryotic promoters is restricted by the structure of chromatin, and activation of transcription is associated with many changes in chromatin structure in the transcribed region. Second, although eukaryotic cells have both positive and negative regulatory mechanisms, positive mechanisms predominate in all systems characterized so far. Thus, given that the transcriptional ground state is restrictive, virtually every eukaryotic gene requires activation in order to be transcribed. Third, eukaryotic cells have larger, more complex multimeric regulatory proteins than do bacteria. Finally, transcription in the eukaryotic nucleus is separated from translation in the cytoplasm in both space and time. The complexity of regulatory circuits in eukaryotic cells is extraordinary, as the following discussion shows. We conclude the section with an illustrated description of one of the most elaborate circuits: the regulatory cascade that controls development in fruit flies.

Transcriptionally Active Chromatin Is Structurally Distinct from Inactive Chromatin

The effects of chromosome structure on gene regulation in eukaryotes have no clear parallel in bacteria. In the eukaryotic cell cycle, interphase chromosomes appear, at first viewing, to be dispersed and amorphous (see Fig. 24-24). Nevertheless, several forms of chromatin can be found along these chromosomes. About 10% of the chromatin in a typical eukaryotic cell is in a more condensed form than the rest of the chromatin.

This form, heterochromatin, is transcriptionally inactive. Heterochromatin is generally associated with particular chromosome structures—the centromeres, for example. The remaining, less condensed chromatin is called euchromatin. Transcription of a eukaryotic gene is strongly repressed when its DNA is condensed within heterochromatin. Some, but not all, of the euchromatin is transcriptionally active. Transcriptionally active chromosomal regions are distinguished from heterochromatin in at least three ways: the positioning of nucleosomes, the presence of histone variants, and the covalent modification of nucleosomes. These transcription-associated structural changes in chromatin are collectively called chromatin remodeling. The remodeling involves enzymes that promote these changes (Table 28-2). Five known families of enzyme complexes actively reposition or displace nucleosomes, hydrolyzing ATP in the process. Three of these are particularly important in transcriptional activation (Table 28-2; see the table footnote for an explanation of the abbreviated names of the enzyme complexes described here). SWI/SNF, found in all eukaryotic cells, contains at least six core polypeptides that together remodel chromatin so that nucleosomes become more irregularly spaced. They also stimulate transcription factor binding. The complex includes a component called a bromodomain near the carboxyl terminus of the active ATPase subunit, which interacts with acetylated histone tails. SWI/SNF is not required for the transcription of every gene. NURF, a member of the ISW1 family, remodels chromatin in ways that complement and overlap the activity of SWI/SNF. These two enzyme complexes are crucial in preparing a region of chromatin for active transcription. The third important protein family has a somewhat different role. Transcriptionally active chromatin tends to be deficient in histone H1, which binds to the linker DNA between nucleosome particles. These regions of chromatin are also enriched in the histone variants H3.3 and H2AZ (see Box 24-2). Alterations in histone content are again mediated by specialized enzymes and protein complexes. H2AZ deposition involves members of this third family of ATP-dependent remodeling enzymes, called SWR1. The covalent modification of histones is altered dramatically within transcriptionally active chromatin. The core histones of nucleosome particles (H2A, H2B, H3, H4; see Fig. 24-26) are modified by

methylation of Lys or Arg residues, phosphorylation of Ser or Thr residues, acetylation (see below), ubiquitination (see Fig. 27-47), or sumoylation. Each of the core histones has two distinct structural domains. A central domain is involved in histone-histone interaction and the wrapping of DNA around the nucleosome. A second, lysine-rich amino-terminal domain is generally positioned near the exterior of the assembled nucleosome particle; the covalent modifications occur at specific residues concentrated in this amino-terminal domain. The patterns of modification have led some researchers to propose the existence of a histone code, in which modification patterns are recognized by enzymes that alter the structure of chromatin. Indeed, some of the modifications are essential for interactions with proteins that play key roles in transcription. The acetylation and methylation of histones figure prominently in the processes that activate chromatin

1176 Regulation of Gene Expression | TABLE 28-2 | "A:TA

Some Enzyme Complexes Catalyzing Chromatin Structural Changes Associated with Transcription

Oligomeric structure	Enzyme complex*	(number of polypeptides)	Source	Activities
Histone modification	GCN5-ADA2-ADA3	3	Yeast	GCN5 has type A HAT activity

SWRI family	~12	Eukaryotes	H2AZ deposition	
Histone chaperones that do not require ATP	HIRA	1	Eukaryotes	Deposition of H3.3 during transcription

The abbreviations for eukaryotic genes and proteins are often more confusing or obscure than those used for bacteria. The complex of GCNS (general control nonderepressible) and ADA (alteration/deficiency activation) proteins was discovered during investigation of the regulation of nitrogen metabolism genes in yeast. These proteins can be part of the larger SAGA complex (SPF, ADA2,3, GCN5, acetyltransferase) in yeasts. The equivalent of SAGA in humans is PCAF (300/CBP- associated factor). NuA4 is nucleosome acetyltransferase of H4; ESA1 is essential SAS2-related acetyltransferase. SWI (switching) was discovered as a protein required for expression of certain genes involved in mating-type switching in yeast, and SNF (sucrose nonfermenting) as a factor for expression of the yeast gene for sucrase. Subsequent studies revealed multiple SWI and SNF proteins that acted in a complex. The SWI/SNF complex has a role in the expression of a wide range of genes and has been found in many eukaryotes, including humans. ISWI is imitation SWI; NURF, nuclear remodeling factor; SWR1, Swi2/Snf2-related ATPase 1; and HIRA, histone regulator A. for transcription. During transcription, histone H3 is methylated (by specific histone methylases) at Lys in nucleosomes near the 5' end of the coding region and at Lys" throughout the coding region. These methylations facilitate the binding of histone acetyltransferases (HATs), enzymes that acetylate particular Lys residues. Cytosolic (type B) HATs acetylate newly synthesized

histones before the histones are imported into the nucleus. The subsequent assembly of the histones into chromatin after replication is facilitated by histone chaperones: CAF1 for H3 and H4 (see Box 24-2), and NAP1 for H2A and H2B. Where chromatin is being activated for transcription, the nucleosomal histones are further acetylated by nuclear (type A) HATs. The acetylation of multiple Lys residues in the amino-terminal domains of histones H3 and H4 can reduce the affinity of the entire nucleosome for DNA.

Acetylation of particular Lys residues is critical for the interaction of nucleosomes with other proteins. When transcription of a gene is no longer required, the extent of acetylation of nucleosomes in that vicinity is reduced by the activity of histone deacetylases (HDACs), as part of a general gene-silencing process that restores the chromatin to a transcriptionally inactive state. In addition to the removal of certain acetyl groups, new covalent modification of histones marks chromatin as transcriptionally inactive. For example, Lys' of histone H3 is often methylated in heterochromatin. The net effect of chromatin remodeling in the context of transcription is to make a segment of the chromosome more accessible and to "label" (chemically modify) it so as to facilitate the binding and activity of transcription factors that regulate expression of the gene or genes in that region. Most Eukaryotic Promoters Are Positively Regulated As already noted, eukaryotic RNA polymerases have little or no intrinsic affinity for their promoters; initiation of transcription is almost always dependent on the action of multiple activator proteins. One important reason for the apparent predominance of positive regulation seems obvious: the storage of DNA within chromatin effectively renders most promoters inaccessible, so genes are silent in the absence of other regulation. The structure of chromatin affects access to some promoters more than others, but repressors that bind to DNA so as to preclude access of RNA polymerase

(negative regulation) would often be simply redundant. Other factors must be at play in the use of positive regulation, and speculation generally centers around two: the large size of eukaryotic genomes and the greater efficiency of positive regulation. First, nonspecific DNA binding of regulatory proteins becomes a more important problem in the much larger genomes of higher eukaryotes. And the chance that a single specific binding sequence will occur randomly at an inappropriate site also increases with genome size. Combinatorial control thus becomes important in a large genome (Fig. 28-27). Specificity for transcriptional activation can be improved if each of several positive-regulatory proteins must bind specific DNA sequences in order to activate a gene. The average number of regulatory sites for a gene in a multicellular organism is six, and genes that are regulated by a dozen such sites are common. The requirement for binding of several positive-regulatory proteins to specific DNA sequences vastly reduces the probability of the random occurrence of a functional juxtaposition of all the necessary binding sites. In addition, the actual number of regulatory proteins that must be encoded by a genome to regulate all of its genes can be reduced (Fig. 28-27). Thus, a new regulator is not needed for every gene, although regulation is complex enough in higher eukaryotes that regulator proteins may represent 5% to 10% of 13 14 15 19 20 21 25 26 27

FIGURE 28-27 The advantages of combinatorial control. Combinatorial control allows specific regulation of many genes using a limited repertoire of regulatory proteins. Consider the possibilities inherent in regulation by two different families of leucine zipper proteins (red and green). If each regulatory gene family has three members (shown here as dark, medium, and light shades, each binding to a different DNA sequence) that can freely form either homo- or heterodimers, there are six possible dimeric

1177 28.3 Regulation of Gene Expression in Eukaryotes all protein-encoding genes. In principle, a similar combinatorial strategy could be used by multiple negativeregulatory elements, but this brings us to the second reason for the use of positive regulation: it is simply more efficient. If the ~25,000 genes in the human genome were negatively regulated, each cell would have to synthesize, at all times, all of the different repressors in concentrations sufficient to permit specific binding to each “unwanted” gene. In positive

regulation, most of the genes are usually inactive (that is, RNA polymerases do not bind to the promoters) and the cell synthesizes only the activator proteins needed to promote transcription of the subset of genes required in the cell at that time. These arguments notwithstanding, there are examples of negative regulation in eukaryotes, from yeasts to humans, as we shall see.

DNA-Binding Activators and Coactivators Facilitate Assembly of the General Transcription Factors

To continue our exploration of the regulation of gene expression in eukaryotes, we return to the interactions between promoters and RNA polymerase II (Pol II), the enzyme responsible for the synthesis of eukaryotic mRNAs. Although many (but not all) Pol II promoters include the TATA box and Inr (initiator) sequences, with their standard spacing (see Fig. 26-8), they vary within species in each family, each of which would recognize a different bipartite regulatory DNA sequence. If a gene had a regulatory site for each protein family, 36 different regulatory combinations would be possible, using just the six proteins from these two families. With six or more sites used in the regulation of a typical eukaryotic gene, the number of possible variants is much greater than this example suggests.

1178 Regulation of Gene Expression greatly in both the number and the location of additional sequences required for the regulation of transcription. The additional regulatory sequences, generally bound by transcription activators, are usually called enhancers in higher eukaryotes and upstream activator sequences (UASs) in yeast. A typical enhancer may be found hundreds or even thousands of base pairs upstream from the transcription start site, or may even be downstream, within the gene itself. When bound by the appropriate regulatory proteins, an enhancer increases transcription at nearby promoters regardless of its orientation in the DNA. The UASs of yeast function in a similar way, although generally they must be positioned upstream and within a few hundred base pairs of the transcription start site. Successful binding of active RNA polymerase II holoenzyme at one of its promoters usually requires the combined action of proteins of five types that have now been described: (1) transcription activators, which bind to enhancers or UASs and facilitate transcription; (2) architectural regulators that facilitate DNA looping; (3) chromatin modification and remodeling proteins, described above; (4) coactivators; and (5) basal transcription factors (see Fig. 26-9, Table 26-2), required at most Pol II promoters (Fig. 28-28). The coactivators act indirectly—not by binding to the DNA—and are required for essential communication between the activators and the complex composed of Pol II and the basal (or general) transcription factors. Furthermore, a variety of repressor proteins can interfere with communication between the RNA polymerase and the activators, resulting in repression of transcription (Fig. 28-28b). Here we focus on the protein complexes

FIGURE 28-28 Eukaryotic promoters and regulatory proteins. RNA polymerase II and its associated basal (general) transcription factors form a preinitiation complex at the TATA box and Inr site of the cognate promoters, a process facilitated by transcription activators, acting through coactivators (Mediator, TFIID, or both). (a) A composite promoter with typical sequence elements and protein complexes found in both yeast and higher eukaryotes. The carboxyl-terminal domain (CTD) of Pol II (see Fig. 26-9) is an important point of interaction with Mediator and other protein complexes. Histone modification enzymes (not shown) catalyze methylation and acetylation; remodeling enzymes alter the content and placement of nucleosomes. The transcription

activators have distinct DNA-binding domains and activation domains. Green arrows indicate common modes of interaction often required for the activation of transcription, as discussed in the text. The HMG proteins are a common type of architectural regulator (see Fig. 28-5), facilitating the looping of the DNA required to bring together system components bound at distant binding sites. (b) Eukaryotic transcriptional repressors function by a range of mechanisms. Some bind directly to DNA, displacing a protein complex required for activation (not shown); many others interact with various parts of the transcription or activation protein complexes to prevent activation. Possible points of interaction are indicated with red arrows. (c) The structure of an HMG protein complex with DNA shows how HMG proteins facilitate DNA looping. The binding is relatively nonspecific, although DNA sequence preferences have been identified for many HMG proteins. Shown is the HMG domain of the protein HMG-D of *Drosophila*, bound to DNA (PDB ID 1QRV). shown in Figure 28-28 and on how they interact to activate transcription.

Transcription Activators The requirements for activators vary greatly from one promoter to another. A few activators are known to facilitate transcription at hundreds of promoters, whereas others are specific for a few promoters. Many activators are sensitive to the binding of signal molecules, providing the capacity to activate or deactivate transcription in response to a changing cellular environment. Some enhancers bound by activators are quite distant from the promoter's TATA box. Multiple (a) Activation HMG proteins UAS DNA Transcription activators and coactivators Pol II initiation complex (b) Repression DNA (Mediator. À ie. © (c) HMG domain

enhancers (often six or more) are bound by a similar number of activators for a typical gene, providing combinatorial control and response to multiple signals. Architectural Regulators

How do the activators function at a distance? The answer in most cases seems to be that, as indicated earlier, the intervening DNA is looped so that the various protein complexes can interact directly. The looping is promoted by architectural regulators that are abundant in chromatin and bind to DNA with limited specificity. Most prominently, the high mobility group (HMG) proteins (Fig. 28-28c; “high mobility” refers to their electrophoretic mobility in polyacrylamide gels) play an important structural role in chromatin remodeling and transcriptional activation.

Coactivator Protein Complexes Most transcription requires the presence of additional protein complexes. Some major regulatory protein complexes that interact with Pol II have been defined both genetically and biochemically. These coactivator complexes act as intermediaries between the transcription activators and the Pol II complex. A major eukaryotic coactivator, consisting of 20 to 30 or more polypeptides in a protein complex, is called Mediator (Fig. 28-28). Many of the 20 core polypeptides are highly conserved from fungi to humans. An additional complex of four subunits can interact with Mediator and inhibit transcription initiation. Mediator binds tightly to the carboxyl-terminal domain (CTD) of the largest subunit of Pol II. The Mediator complex is required for both basal and regulated transcription at many promoters used by Pol II, and it also stimulates phosphorylation of the CTD by TFIIF (a basal transcription factor). Transcription activators interact with one or more components of the Mediator complex, with the precise interaction sites differing from one activator to another. Coactivator complexes function at or near the promoter’s TATA box. Additional coactivators, functioning with one or a few genes, have also been described. Some of these operate in conjunction with Mediator, and some may act in systems that do not employ Mediator.

TATA-Binding Protein The first component to bind in the assembly of a preinitiation complex (PIC) at the TATA box of a typical Pol II promoter is the TATA-binding protein (TBP). TBP is often, but not always, delivered as part of a larger complex (~15 subunits) called TFIID. The complete complex also includes the basal transcription factors TFIIB, TFIIA, TFIIF, TFIH; Pol II; and perhaps TFIID. This

minimal PIC, however, is often insufficient for the initiation of transcription and generally does not form at all if the promoter is obscured

FIGURE 28-29 The components of transcriptional activation. Activators bind the DNA first. The activators recruit the histone modification/nucleosome remodeling complexes and a coactivator such as Mediator. Mediator facilitates the binding of TBP (or TFIID) and TFIIB, and the other basal transcription factors and Pol II then bind. Phosphorylation of the carboxyl-terminal domain (CTD) of Pol II leads to transcription initiation (not shown).

28.3 Regulation of Gene Expression in Eukaryotes 1179

within chromatin. Positive regulation, leading to transcription, is imposed by the activators and coactivators.

Choreography of Transcriptional Activation

We can now begin to piece together the sequence of transcriptional activation events at a typical Pol II promoter (Fig. 28-29).

TATA Inr | TATA Inr Activator Enhancer Mediator

Modification and remodeling enzymes

Modification and remodeling complex

1180 Regulation of Gene Expression The exact order of binding of some components may vary, but the model in Figure 28-29 illustrates the principles of activation as well as one common path. Many transcription activators have significant affinity for their binding sites even when the sites are within condensed chromatin. The binding of activators is often the event that triggers subsequent activation of the promoter. Binding of one activator may enable the binding of others, gradually displacing some nucleosomes. Crucial remodeling of the chromatin then takes place in stages, facilitated by interactions between activators and HATs or enzyme complexes such as SWI/ SNF (or both). In this way, a bound activator can draw in other components necessary for further chromatin remodeling to permit transcription of specific genes. The bound activators interact with the large Mediator complex. Mediator, in turn, provides an assembly surface for the binding of first TBP (or TFIID), then TFIIB, and then other components of the PIC, including RNA polymerase II. Mediator stabilizes the binding of Pol II and its associated transcription factors and greatly facilitates formation of the PIC. Complexity in these regulatory circuits is the rule rather than the exception, with multiple DNA-bound activators promoting transcription. The script can change from one promoter to another. For example, many promoters have a different set of recognition sequences and may not have a TATA box, and in multicellular eukaryotes the subunit composition of factors such as TFIID can vary from one tissue to another. However, most promoters seem to require a precisely ordered assembly of components to initiate transcription. The assembly process is not always fast. At some genes it may take minutes; at certain genes of higher eukaryotes the process can take days.

Reversible Transcriptional Activation Although rarer, some eukaryotic regulatory proteins that bind to Pol II promoters or that interact with transcriptional activators can act as repressors, inhibiting the formation of active PICs (Fig. 28-29). Some activators can adopt different conformations, enabling them to serve as transcription activators or as repressors. For example, some steroid hormone receptors (described later) function in the nucleus as transcription activators, stimulating the transcription of certain genes when a particular steroid hormone signal is present. When the hormone is absent, the receptor proteins revert to a repressor conformation,

preventing the formation of PICs. In some cases this repression involves interaction with histone deacetylases and other proteins that help restore the surrounding chromatin to its transcriptionally inactive state. Mediator, when it includes the inhibitory subunits, may also block transcription initiation. This may be a regulatory mechanism to ensure ordered assembly of the PIC (by delaying transcriptional activation until all required factors are present), or it may be a mechanism that helps deactivate promoters when transcription is no longer required. The Genes of Galactose Metabolism in Yeast Are Subject to Both Positive and Negative Regulation Some of the general principles described above can be illustrated by one well-studied eukaryotic regulatory circuit (Fig. 28-30). The enzymes required for the importation and metabolism of galactose in yeast are TATA Inr UASgal Gal3p + Galactose | SAGA | Galactose Mediator | TFIID |

FIGURE 28-30 Regulation of transcription of GAL genes in yeast. Galactose imported into the yeast cell is converted to galactose 6-phosphate by a pathway involving six enzymes, whose genes are scattered over three chromosomes (see Table 28-3). Transcription of these genes is regulated by the combined actions of the proteins Gal4p, Gal80p, and Gal3p, with Gal4p playing the central role of transcription activator. The Gal4p-Gal80p complex is inactive. Binding of galactose to Gal3p leads to interaction of Gal3p with the Gal80p-Gal4p complex and activates Gal4p. The Gal4p subsequently recruits SAGA, Mediator, and TFIID to the galactose promoters, leading to DNA polymerase II recruitment and initiation of transcription.

encoded by genes scattered over several chromosomes (Table 28-3).

Each of the GAL genes is transcribed separately, and yeast cells

have no operons like those in bacteria. However, all the GAL genes

have similar promoters and are regulated coordinately by a

common set of proteins. The promoters for the GAL genes consist of

the TATA box and Inr sequences, as well as an upstream activator

sequence (UASg) recognized by the transcription activator Gal4

protein (Gal4p). Regulation of gene expression by galactose entails

an interplay between Gal4p and two other proteins, Gal80p and

Gal3p (Fig. 28-30). Gal80p forms a complex with Gal4p, preventing

Gal4p from functioning as an activator of the GAL promoters. When

galactose is present, it binds Gal8p, which then interacts with the

Gal80p-Gal4p complex, allowing Gal4p to function as an activator

at the various GAL promoters. As the various galactose genes are

induced and their products build up, Gal3p may be replaced with

Gallp (a galactokinase needed for galactose metabolism that also

functions in regulation) for sustained activation of the regulatory

circuit. Other protein complexes also have a role in activating

transcription of the GAL genes. These include the SAGA complex for

histone acetylation and chromatin remodeling, the SWI/SNF

complex for chromatin remodeling, and the Mediator complex. The

Gal4 protein is responsible for the recruitment of these additional

factors needed for transcriptional activation. SAGA may be the first

and primary recruitment target for Gal4p. Glucose is the preferred

carbon source for yeast, as it is for bacteria. When glucose is

present, most of the GAL genes are repressed—whether galactose is present or not. The GAL regulatory system described above is effectively overridden by a complex catabolite repression system that includes several proteins (not depicted in Fig. 28-30).

Transcription Activators Have a Modular Structure Transcription activators typically have a distinct structural domain for specific DNA binding and one or more additional domains for transcriptional activation or for interaction with other regulatory proteins. Interaction of two regulatory proteins is often mediated by domains containing leucine zippers (Fig. 28-14) or helix-loop-helix motifs (Fig. 28-15). We consider here three distinct types of structural domains used in activation by transcription activators (Fig. 28-31a): Gal4p, Spl, and CTF1. Gal4p contains a zinc finger-like structure in its DNA-binding domain, near the amino terminus; this domain has six Cys residues that coordinate two Zn²⁺. The protein functions as a homodimer (with dimerization mediated by interactions between two coiled coils) and binds to UASg, a palindromic DNA sequence about 17 bp long. Gal4p has a separate activation domain with many acidic amino acid residues.

Experiments that substitute a variety of different peptide sequences for the acidic activation domain of Gal4p suggest that the acidic nature of this domain is critical to its function, although its precise amino acid sequence can vary considerably. Spl (M, 80,000) is a transcription activator for a large number of genes in higher eukaryotes. Its DNA-binding site, the GC box (consensus sequence GGGCGG), is usually quite near the TATA box. The DNA-binding domain of the Sp1 protein is near its carboxyl terminus

1182 Regulation of Gene Expression FIGURE 28-31

Transcription activators. (a) Typical activators such as CTF1, Gal4p, and Sp1 have a DNA-binding domain and an activation domain. The nature of the activation domain is indicated by symbols: — — ~ = , acidic; Q Q Q, glutamine-rich; P P P, proline-rich. These proteins generally activate transcription by interacting with coactivator complexes such as Mediator. Note that the binding sites illustrated here are not generally found together near a single gene. (b) A chimeric protein containing the DNA-binding domain of Sp1 and the activation domain of CTF1 activates transcription if a GC box is present. and contains three zinc fingers. Two other domains in Sp1 function in activation and are notable in that 25% of their amino acid residues are Gln. A wide variety of other activator proteins also have these glutaminerich domains. CTF1 (CCAAT-binding transcription factor 1) belongs to a family of transcription activators that bind a sequence called the CCAAT site (its consensus sequence is TGGNgGCCAA, where N is any nucleotide). The DNA-binding domain of CTF1 contains many basic amino acid residues, and the binding region is probably arranged as an a helix. This protein has neither a helixturn-helix nor a zinc finger motif; its DNA-binding mechanism is not yet clear. CTF1 has a proline-rich activation domain, with Pro accounting for more than 20% of the amino acid residues. The discrete activation and DNA-binding domains of regulatory proteins often act completely independently, as has been demonstrated in “domain-swapping” experiments. Genetic engineering techniques (Chapter 9) can join the proline-rich activation domain of CTF 1 to the DNA-binding domain of Sp1 to create a protein that, like intact Sp1, binds to GC boxes on the DNA and activates transcription at a nearby promoter (as in Fig. 28-31b). The DNA-binding domain of Gal4p has similarly been replaced experimentally with the DNA-binding domain of the *E. coli* LexA repressor (of the SOS response; Fig. 28-20). This chimeric protein neither binds at UASg nor activates the yeast GAL genes (as would intact Gal4p) unless the UASg sequence in the DNA is replaced by the LexA recognition site. Eukaryotic Gene Expression Can Be Regulated by Intercellular and Intracellular Signals The effects of steroid hormones (and of thyroid and retinoid hormones, which have a similar mode of action) provide additional well-studied examples of the modulation of eukaryotic regulatory proteins by

direct interaction with molecular signals (see Fig. 12-30). Unlike other types of hormones, steroid hormones do not have to bind to plasma membrane receptors. Instead, they can interact with intracellular receptors that are themselves transcription activators. Steroid hormones too hydrophobic to dissolve readily in the blood (estrogen, progesterone, and cortisol, for example) travel on specific carrier proteins from their point of release to their target tissues. In the target tissue, the hormone passes through the plasma membrane by simple diffusion. Once inside the cell, the hormones interact with one of two types of steroid-binding nuclear receptor (Fig. 28-32). In both cases, the hormone-receptor complex acts by binding to highly specific DNA sequences called hormone response elements (HREs), thereby altering gene expression. Acting at these sites, the receptors act as transcription activators, recruiting coactivators and DNA polymerase II (plus its associated transcription factors) to trigger transcription of the gene. The DNA sequences (HREs) to which hormone-receptor complexes bind are similar in length and arrangement, but differ in sequence, for the various steroid hormones. Each receptor has a consensus HRE sequence (Table 28-4) to which the hormone-receptor complex binds well, with each consensus consisting of two six-nucleotide sequences, either contiguous or separated by three nucleotides, in tandem or in a palindromic arrangement. The hormone receptors have a highly conserved DNA-binding domain with two zinc fingers (Fig. 28-33). The hormone-receptor complex binds to the DNA as a dimer, with the zinc finger domains of each monomer recognizing one of the six-nucleotide sequences. The ability of a given hormone to act through the hormone-receptor complex to alter the expression of a specific gene depends on the exact sequence of the HRE, its position relative to the gene, and the number of HREs associated with the gene. The ligand-binding region of the receptor protein—always at the carboxyl terminus—is quite specific to the particular receptor. In the ligand-binding region, the

FIGURE 28-32 Mechanisms of steroid hormone receptor function. There are two types of steroid-binding nuclear receptors. (a) Monomeric type | receptors (NR) are found in the cytoplasm, in a complex with a heat shock protein (Hsp70). Receptors for estrogen, progesterone, androgens, and glucocorticoids are of this type. When the steroid hormone binds, the Hsp70 dissociates and the receptor dimerizes, exposing a nuclear localization signal. The dimeric receptor, with hormone bound, migrates to the nucleus, where it binds a hormone response element (HRE) and acts as a transcription activator. (b) Type II receptors, by contrast, are always in the nucleus, bound to an HRE in the DNA and to a corepressor that renders them inactive. The thyroid hormone receptor (TR) is of this type. The hormone migrates through the cytoplasm and diffuses across the nuclear membrane. In the nucleus it binds to a heterodimer consisting of the thyroid hormone receptor and the retinoid X receptor (RXR). A conformation change leads to dissociation of the corepressor, and the receptor then functions as a transcription activator.

FIGURE 28-33 Typical steroid hormone receptors. These receptor proteins have a binding site for the hormone, a DNA-binding domain, and a region that activates transcription of the regulated gene. The highly conserved DNA-binding domain has two zinc fingers. The sequence shown here is that for the estrogen receptor, but the residues in bold type are common to all steroid hormone receptors.

1184 Regulation of Gene Expression as part of a ribonucleoprotein complex, but it is the RNA component that is required for transcription coactivation. The detailed set of interactions between SRA and other components of the regulatory systems for these genes remains to be worked out. Regulation Can Result from Phosphorylation of Nuclear Transcription Factors We noted in Chapter 12 that the effects of insulin on gene expression are mediated by a series of steps leading ultimately to the activation of a protein kinase in the nucleus that phosphorylates specific DNA-binding proteins and thereby alters their ability to act as transcription factors (see Fig. 12-15). This general mechanism mediates the effects of many nonsteroid hormones. For example, the B-adrenergic pathway that leads to elevated levels of cytosolic cAMP, which acts as a second messenger in eukaryotes as well as in bacteria (see Figs 12-4, 28-17), also affects the transcription of a set of genes, each of which is located near a specific DNA sequence called a cAMP response element (CRE). The catalytic subunit of protein kinase A, released when cAMP levels rise (see Fig. 12-6), enters the nucleus and phosphorylates a nuclear protein, the CRE-binding protein (CREB). When phosphorylated, CREB binds to CREs near certain genes and acts as a transcription factor, turning on the expression of these genes. Many Eukaryotic mRNAs Are Subject to Translational Repression Regulation at the level of translation assumes a much more prominent role in eukaryotes than in bacteria and is observed in a range of cellular situations. In contrast to the tight coupling of transcription and translation in bacteria, the transcripts generated in a eukaryotic nucleus must be processed and transported to the cytoplasm before translation. This can impose a significant delay on the appearance of a protein. When a rapid increase in protein production is needed, a translationally repressed mRNA already in the cytoplasm can be activated for translation without delay. Translational regulation may play an especially important role in regulating certain very long eukaryotic genes (a few are measured in the millions of base pairs), for which transcription and mRNA processing can require many hours. Some genes are regulated at both the transcriptional and translational stages, with the latter playing a role in the fine-tuning of cellular protein levels. In some anucleate cells, such as reticulocytes (immature erythrocytes), transcriptional control is entirely

unavailable and translational control of stored mRNAs becomes essential. As described below, translational controls can also have spatial significance during development, when the regulated translation of prepositioned mRNAs creates a local gradient of the protein product.

3' untranslated region (UTR) Poly(A) binding protein (PAB)

Translational repressors

FIGURE 28-34 Translational regulation of eukaryotic mRNA.

One of the most important mechanisms for translational regulation in eukaryotes involves the binding of translational repressors (RNA-binding proteins) to specific sites in the 3' untranslated region (3'UTR) of the mRNA. These proteins interact with eukaryotic initiation factors or with the ribosome to prevent or slow translation. Eukaryotes have at least four main mechanisms of translational regulation.

1. Translation initiation factors are subject to phosphorylation by protein kinases. The phosphorylated forms are often less active and cause a general depression of translation in the cell.
2. Some proteins bind directly to mRNA and act as translational repressors, many of them binding at specific sites in the 3' untranslated region (3'UTR). So positioned, these proteins interact with other translation initiation factors bound to the mRNA or with the 40S ribosomal subunit to prevent translation initiation (Fig. 28-34).
3. Binding proteins, present in eukaryotes from yeast to mammals, disrupt the interaction between eIF4E and eIF4G (see Fig. 27-28). The mammalian versions are known as 4E-BPs (eIF4E binding proteins). When cell growth is slow, these proteins limit translation by binding to the site on eIF4E that normally interacts with eIF4G. When cell growth resumes or increases in response to growth factors or other stimuli, the binding proteins are inactivated by protein kinase—dependent phosphorylation.
4. RNA-mediated regulation of gene expression, considered later, often occurs at the level of translational repression. The variety of translational regulation mechanisms provides flexibility, allowing focused repression of a few mRNAs or global regulation of all cellular translation. Translational regulation has been particularly well studied in reticulocytes. One such mechanism in these cells involves eIF2, the initiation factor that binds to the initiator tRNA and conveys it to the ribosome; when

Met-tRNA has bound to the P site, the factor eIF2B binds to eIF2, recycling it with the aid of GTP binding and hydrolysis. The maturation of reticulocytes includes destruction of the cell nucleus, leaving behind a plasma membrane packed with hemoglobin. Messenger RNAs deposited in the cytoplasm before the loss of the nucleus allow for the replacement of hemoglobin. When reticulocytes become deficient in iron or heme, the translation of globin mRNAs is repressed. A protein kinase called HCR (hemin-controlled repressor) is activated, catalyzing the phosphorylation of eIF2. When phosphorylated, eIF2 forms a stable complex with eIF2B that sequesters the eIF2, making it unavailable for participation in translation. In this way, the reticulocyte coordinates the synthesis of globin with the availability of heme. Many additional examples of translational regulation have been found in studies of the development of multicellular organisms, as discussed in more detail below.

Posttranscriptional Gene Silencing Is Mediated by RNA Interference In higher eukaryotes, including nematodes, fruit flies, plants, and mammals, a class of small RNAs called microRNAs (miRNAs) mediates the silencing of many genes. In a phenomenon first described and explained by Craig Mello and Andrew Fire, the RNAs function by interacting with mRNAs, often in the 3'UTR, resulting in either mRNA degradation or translation inhibition. In either case, the mRNA, and thus the gene that produces it, is silenced. This form of gene _ regulation controls developmental timing in at least some organisms. It is also used as a mechanism to protect against invading RNA viruses (particularly important in plants, which lack an immune system) and to control the activity of transposons. In addition, small RNA molecules may play a critical (but still undefined) role in the formation of heterochromatin. Many miRNAs are present only transiently during development, and these are sometimes referred to as small temporal RNAs (stRNAs). Thousands of different miRNAs have been identified in higher eukaryotes, and they may affect the regulation of a third of mammalian genes. They are transcribed as precursor RNAs about 70 nucleotides long, with internally complementary sequences that form hairpinlike structures. Details of the pathway for processing of miRNAs were described in Chapter 26 (see Fig. 26-27). The precursors are cleaved by endonucleases such as Dro

Craig Mello
Andrew Fire

28.3 Regulation of Gene Expression in Eukaryotes

1185 sha and Dicer to form short duplexes about 20 to 25 nucleotides long. One strand of the processed miRNA is transferred to the target mRNA (or to a viral or transposon RNA), leading to inhibition of translation or degradation of the RNA (Fig. 28-35). Some miRNAs bind to and affect a single mRNA and thus affect expression of only one gene. Others interact with multiple mRNAs and thus form the mechanistic core of regulons that coordinate the expression of multiple genes. This gene regulation mechanism has an interesting and very useful practical side. If an investigator introduces into an organism a duplex RNA molecule corresponding in sequence to virtually any mRNA, Dicer cleaves the duplex into short segments, called small interfering RNAs (siRNAs). These bind to the mRNA and silence it (Fig. 28-35b). The process is known as RNA interference (RNAi). In plants, virtually any gene can be effectively shut down in this way. Nematodes readily ingest entire, functional RNAs, and simply introducing the duplex RNA into the worm's diet produces very effective suppression of the target gene. The technique has rapidly become an important tool in the ongoing efforts to study gene function, because it can disrupt gene function without creating a mutant organism. The procedure can be applied to humans as well. Laboratory-produced siRNAs have been used to block HIV and poliovirus infections in cultured human cells (a) (b)

Precursor | : : | Duplex RNA Dicer Dicer TOL.. stRNA siRNA En / AAA(A), Silenced it \ Degradation Translation inhibition

FIGURE 28-35 Gene silencing by RNA interference. (a) Small temporal RNAs (stRNAs, a class of miRNAs) are generated by Dicer-mediated cleavage of longer precursors that fold to create duplex regions. The stRNAs then bind to mRNAs, leading to degradation of mRNA or inhibition of translation. (b) Double-stranded RNAs can be constructed and introduced into a cell. Dicer processes the duplex RNAs into small interfering RNAs (siRNAs), which interact with the target mRNA. Again, either the mRNA is degraded or translation is inhibited.

1186 Regulation of Gene Expression for a week or so at a time. Rapid progress in research into RNA interference makes this a field to watch for future medical advances. RNA-Mediated Regulation of Gene Expression Takes Many Forms in Eukaryotes

The special-function RNAs in eukaryotes include miRNAs, described above; snRNAs, involved in RNA splicing (see Fig. 26-16); and snoRNAs, involved in rRNA modification (see Fig. 26-25). All RNAs that do not encode proteins, including rRNAs and tRNAs, come under the general designation of ncRNAs (noncoding RNAs). Mammalian genomes seem to encode more ncRNAs than coding mRNAs (see Box 26-4). Not surprisingly, additional functional classes of ncRNAs are still being discovered. Many of the newly found examples interact with proteins rather than with RNAs and affect the function of the bound proteins. The SRA that functions as a coactivator of steroid hormone-responsive genes is one example: it affects the activation of transcription. The heat shock response in human cells provides another example. Heat shock factor 1 (HSF1) is an activator protein that, in nonstressed cells, exists as a monomer bound by the chaperone Hsp90. Under stress conditions, HSF1 is released from Hsp90 and trimerizes. The HSF1 trimer binds to DNA and activates transcription of genes whose products are required to deal with the stress. An ncRNA called HSR1 (heat shock RNA 1; ~600 nucleotides) stimulates the HSF1 trimerization and DNA binding. HSR1 does not act alone; it functions in a complex with the translation elongation factor eHF1A. Additional RNAs affect transcription in a variety of ways. Besides its role in splicing (see Fig. 26-16), the snRNA U1 directly binds to the transcription factor TFIIH. Its function in this context is not yet clear, but it may regulate TFIIH or affect the coupling between transcription and splicing, or both. A 331 nucleotide ncRNA called 7SK, abundant in mammals, binds to the Pol II transcription elongation factor pTEFb (see Table 26-2) and represses transcript elongation. Another ncRNA, Early embryo—no segments Embryonic © development

FIGURE 28-36 Life cycle of the fruit fly *Drosophila melanogaster*. *Drosophila* undergoes Day 0 Zygote ®© a complete metamorphosis, which means that Fertilization of the adult insect is radically different in form from its immature stages, a transformation Oocyte © that requires extensive alterations during development. By the late embryonic stage, segments have formed, each containing

specialized structures from which the various appendages and other features of the adult fly will develop. B2 (~178 nucleotides), binds directly to Pol II during heat shock and represses transcription. The B2-bound Pol II assembles into stable PICs, but transcription is blocked. The B2 RNA thus halts the transcription of many genes during heat shock, and the mechanism that allows HSF1-responsive genes to be expressed in the presence of B2 remains to be worked out. The recognized roles of ncRNAs in gene expression and in many other cellular processes are rapidly expanding. At the same time, the study of the biochemistry of gene regulation is becoming much less protein-centric. Development Is Controlled by Cascades of Regulatory Proteins For sheer complexity and intricacy of coordination, the patterns of gene regulation that bring about development of a zygote into a multicellular animal or plant have no peer. Development requires transitions in morphology and protein composition that depend on tightly coordinated changes in expression of the genome. More genes are expressed during early development than in any other part of the life cycle. For example, in the sea urchin, an oocyte has about 18,500 different mRNAs, compared with about 6,000 different mRNAs in the cells of a typical differentiated tissue. The mRNAs in the oocyte give rise to a cascade of events that regulate the expression of many genes across both space and time. Several organisms have emerged as important model systems for the study of development, because they are easy to maintain in a laboratory and have relatively short generation times. These include nematodes, fruit flies, zebra fish, mice, and the plant *Arabidopsis*. This discussion focuses on the development of fruit flies. Our understanding of the molecular events during development of *Drosophila melanogaster* is particularly well advanced and can be used to illustrate patterns and principles of general significance. The life cycle of the fruit fly includes complete metamorphosis during its progression from an embryo to an adult (Fig. 28-36). Among the most important characteristics of the embryo are its polarity (the Late embryo—segmented Day 1 Hatching Three larval stages, 5 larval molts Day 5 Pupation ee Metamorphosis Ti To T3 Ay AaAgAaAsAghy Head | Thorax Abdomen

FIGURE 28-37 Early development in *Drosophila*. During development of the egg, maternal mRNAs (including the bicoid and nanos gene transcripts, discussed in the text) and proteins are deposited in the developing oocyte (unfertilized egg cell) by nurse cells and follicle cells. After fertilization, the two nuclei of the fertilized egg divide in synchrony within the common cytoplasm (syncytium), then migrate to the periphery. Membrane invaginations surround the nuclei to create a monolayer of cells at the periphery; this is the cellular blastoderm stage. During the early nuclear divisions, several nuclei at the far posterior become pole cells, which later become the germ-line cells. anterior and posterior parts of the animal are readily distinguished, as are its dorsal and ventral parts) and its metamerism (the embryo body is made up of serially repeating segments, each with characteristic features). During development, these segments become organized into a head, thorax, and abdomen. Each segment of the adult thorax has a different set of appendages. Development of this complex pattern is under genetic control, and a variety of pattern-regulating genes have been discovered that dramatically affect the organization of the body. The *Drosophila* egg, along with 15 nurse cells, is surrounded by a layer of follicle cells (Fig. 28-37). As the egg cell forms (before fertilization), mRNAs and proteins originating in the nurse and follicle cells are deposited in the egg cell, where some play a critical role in development. Once a fertilized egg is laid, its nucleus divides and the nuclear descendants continue to divide in synchrony every 6 to 10 min. Plasma membranes are not formed around the nuclei, which are distributed within the egg cytoplasm (forming a syncytium). Between the eighth and eleventh rounds of nuclear division, the nuclei migrate to the outer layer of the egg, forming a monolayer of nuclei surrounding the common yolk-rich cytoplasm; this is the syncytial blastoderm. After a few additional divisions, membrane invaginations surround the nuclei to create a layer of cells that form the cellular blastoderm. At this stage, the mitotic cycles in the various cells lose their synchrony. The developmental fate of the cells is determined by the mRNAs and proteins originally deposited in the egg by the nurse and follicle cells. Proteins that, through changes in local concentration or activity, cause the surrounding tissue to take up a particular shape or structure are sometimes referred to as morphogens; they are the

products of pattern-regulating genes. As defined by Christiane Nüsslein-Volhard, Edward B. Lewis, and Eric F. Wieschaus, three major classes of pattern-regulating genes—maternal, segmentation, and homeotic genes—function in successive stages of development to Christiane Nüsslein-Volhard specify the basic features of 28.3 Regulation of Gene Expression in Eukaryotes 1187 Nurse cells Follicle cells Anterior Posterior Mature oocyte |} Zygote nuclear divisions) Syncytium nuclear migration yJ) Syncytial J blastoderm Pole cells membrane invagination Cellular blastoderm

Maternal genes are expressed in the unfertilized egg, and the resulting maternal mRNAs remain dormant until fertilization. These provide most of the proteins needed in very early development, until the cellular blastoderm is formed. Some of the proteins encoded by maternal mRNAs direct the spatial organization of the developing embryo at early stages, establishing its polarity. Segmentation genes, transcribed after fertilization, direct the formation of the proper number of body segments. At least three subclasses of segmentation genes act at successive stages: gap genes divide the developing embryo into several broad regions, and pair-rule genes together with segment polarity genes define 14 stripes that become the 14 segments of a normal embryo. Homeotic genes are expressed still later; they specify which organs and appendages will develop in particular body segments. The many regulatory genes in these three classes direct the development of an adult fly, with a head, thorax, and abdomen, with the proper number of segments, and with the correct appendages on each segment. Although embryogenesis takes about a day to complete, all these genes are activated during the first four hours. Some mRNAs and proteins are present for only a few minutes at specific points during this period. Some of the genes code for transcription factors that affect the expression of other genes in a kind of developmental cascade. Regulation at the level of translation also occurs, and many of the regulatory genes encode translational repressors, most of which bind to the 3'UTR of the mRNA (Fig. 28-34). Because many mRNAs are deposited in the egg long before their translation is required, translational repression provides an especially important avenue for regulation in developmental pathways.

Maternal Genes Some maternal genes are expressed within the nurse and follicle cells, and some in the egg itself. In the unfertilized *Drosophila* egg, the maternal gene products establish two axes—anterior-posterior and dorsal-ventral—and thus define which regions of the radially symmetric egg will develop into the head and abdomen and the top and bottom of the adult fly. If all cells divided to produce two identical daughter cells, multicellular organisms would never be more than a ball of identical cells. The generation of different cell fates requires programmed asymmetric cell divisions. A key event in

very early development is establishment of mRNA and protein gradients along the body axes. Some maternal mRNAs have protein products that diffuse through the cytoplasm to create an asymmetric distribution in the egg. Different cells in the cellular blastoderm therefore inherit different amounts of these proteins, setting the cells on different developmental paths. The products of the maternal mRNAs include transcription activators or repressors as well as translational repressors, all regulating the expression of other pattern-regulating genes. The resulting specific patterns and sequences of gene expression therefore differ between cell lineages, ultimately orchestrating the development of each adult structure. The anterior-posterior axis in *Drosophila* is defined at least in part by the products of the *bicoid* and *nanos* genes. The *bicoid* gene product is a major anterior morphogen, and the *nanos* gene product is a major posterior morphogen. The mRNA from the *bicoid* gene is synthesized by nurse cells and deposited in the unfertilized egg near its anterior pole. Nüsslein-Volhard found that this mRNA is translated soon after fertilization, and the Bicoid protein diffuses through the cell to create, by the seventh nuclear division, a concentration gradient radiating out from the anterior pole (Fig. 28-38a). The Bicoid protein is a transcription factor that activates the expression of several segmentation genes; the protein contains a homeodomain (p. 1163). Bicoid is also a translational repressor that inactivates certain mRNAs. The amounts of Bicoid protein in various parts of the embryo affect the subsequent expression of other genes in a threshold-dependent manner. Genes are transcriptionally activated or translationally repressed only where the Bicoid protein concentration exceeds the threshold. Changes in the shape of the Bicoid concentration gradient have dramatic effects on the body pattern. Lack of Bicoid protein results in development of an embryo with two abdomens but neither head nor thorax (Fig. 28-38b); however, embryos without Bicoid will develop normally if an adequate amount of *bicoid* mRNA is injected into the egg at the appropriate end. The *nanos* gene has an analogous role, but its mRNA is deposited at the posterior end of the egg and the anterior-posterior protein gradient peaks at the posterior pole. The Nanos protein is a translational repressor. A broader look at the effects of maternal genes reveals the outline of a developmental circuit. In addition to the *bicoid* and *nanos* mRNAs, which are deposited in the egg asymmetrically, several other maternal mRNAs

are deposited uniformly throughout the egg cytoplasm. Three of these mRNAs encode the Pumilio, Hunchback, and Caudal proteins, all affected by nanos and bicoid (Fig. 28-39). Caudal and Pumilio are involved in development of the posterior end of the fly. Caudal is a transcription activator with a homeodomain; Pumilio is a translational repressor. Hunchback protein plays an important role in development of the anterior end and is also a transcriptional regulator of a variety of

The graph measures stain intensity. This distribution is essential for normal development of the anterior structures. Translation of mRNA and diffusion of products creates concentration gradients in the embryo. Posterior Anterior Nanos localized near posterior Bicoid localized near anterior Bicoid represses Caudal at anterior. Nanos and Pumilio repress Hunchback at posterior. Bicoid activates Hunchback at anterior. Pumilio is evenly distributed but requires Nanos to repress Hunchback; functions only at posterior. Double-posterior larva (b) (b) If the bcd gene is not expressed by the mother (bcd /bcd~ mutant) and thus no bicoid mRNA is deposited in the egg, the resulting embryo has two posteriors (and soon dies).

genes, in some cases a positive regulator, in other cases negative. Bicoid suppresses translation of caudal at the anterior end and also acts as a transcription activator of hunchback in the cellular blastoderm. Because hunchback is expressed both from maternal mRNAs and from genes in the developing egg, it is considered both a maternal and a segmentation gene. The result of the activities of Bicoid is an increased concentration of Hunchback at the anterior end of the egg. The Nanos and Pumilio proteins act as translational repressors of hunchback, suppressing synthesis of its protein near the posterior end of the egg. Pumilio does not function in the absence of the Nanos protein, and the gradient of Nanos expression confines the activity of both proteins to the posterior region. Translational repression of the

FIGURE 28-39 Regulatory circuits of the anterior-posterior axis in a *Drosophila* egg. The bicoid and nanos mRNAs are localized near the anterior and posterior poles, respectively. The caudal, hunchback, and pumilio mRNAs are distributed evenly throughout the egg cytoplasm. The gradients of Bicoid (Bcd) and Nanos proteins affect the expression of the caudal and hunchback mRNAs as shown, leading to accumulation of Hunchback protein in the anterior and Caudal protein in the

posterior of the egg. Because Pumilio protein requires Nanos protein for its activity as a translational repressor of hunchback, it functions only at the posterior end.

1190 Regulation of Gene Expression hunchback gene leads to degradation of hunchback mRNA near the posterior end. However, lack of Bicoid in the posterior leads to expression of caudal. In this way, the Hunchback and Caudal proteins become asymmetrically distributed in the egg. Segmentation Genes Gap genes, pair-rule genes, and segment polarity genes, three subclasses of segmentation genes in *Drosophila*, are activated at successive stages of embryonic development. Expression of the gap genes is generally regulated by the products of one or more maternal genes. At least some of the gap genes encode transcription factors that affect the expression of other segmentation or (later) homeotic genes. One well-characterized segmentation gene is fushi tarazu (ftz), of the pair-rule subclass. When ftz is deleted, the embryo develops 7 segments instead of the normal 14, each segment twice the normal width. The Fushi-tarazu protein (Ftz) is a transcription activator with a homeodomain. The mRNAs and proteins derived from the normal ftz gene accumulate in a striking pattern of seven stripes that encircle the posterior two-thirds of the embryo (Fig. 28-40). The stripes demarcate the positions of segments that develop later; these segments are eliminated if ftz function is lost. The Ftz protein and a few similar regulatory proteins directly or indirectly regulate the expression of vast numbers of genes in the continuing developmental cascade. Homeotic Genes A set of 8 to 11 homeotic genes directs the formation of particular structures at specific locations in the body plan. These genes are now more commonly referred to as Hox genes, the term derived from "homeobox," the conserved gene sequence that (a) Side view (b) Cross-sectional ftz gene bands dorsal view

These bands (b) appear as dark spots (generated by a radioactive label) in a cross-sectional autoradiograph and demarcate the anterior margins of the segments that will appear in the late embryo. encodes the homeodomain and is present in all of these genes. Despite the name, these are not the only development-related proteins to include a homeodomain (for example, the bicoid gene product described above has a homeodomain), and "Hox" is

more a functional than a structural classification. The Hox genes are organized in genomic clusters. *Drosophila* has one such cluster and mammals have four (Fig. 28-41). The genes in these clusters are remarkably similar from nematodes to humans. In *Drosophila*, each of the Hox genes is (a) (b) *Drosophila* lab HOM-C = pb Dfd Ser Antp Ubx adb-A adb-B z BO m en emn Human ' DaN ' t È Hox-A Al A2 A3 A4 AS A6 A7 Hox-B TE M E E O EO EO O OO OOOO BT B2 "B3 "BA B5 "B6 B7 "B8 B9, Hox-C © O a OOOO O O 2 2 2 L C4 CS C6 cs C9 C10 Cif C2 cB Hox-D D1 D3 D4 D& DI DIO Dil Di2 D13

FIGURE 28-41 The Hox gene clusters and their effects on development. (a) Each Hox gene in the fruit fly is responsible for the development of structures in a defined part of the body and is expressed in defined regions of the embryo, as shown here with color coding. (b) *Drosophila* has one Hox gene cluster; the human genome has four. Many of these genes are highly conserved in multicellular animals. Evolutionary relationships, as indicated by sequence alignments, between genes in the *Drosophila* Hox gene cluster and those in the mammalian Hox gene clusters are shown by dashed lines. Similar relationships among the four sets of mammalian Hox genes are indicated by vertical alignment.

(a) FIGURE 28-42 Effects of mutations in Hox genes in *Drosophila*. (a) Normal head. (b) Homeotic mutant (antennapedia) in which antennae are replaced by legs. (c) Normal body structure. (d) Homeotic mutant expressed in a particular segment of the embryo and controls the development of the corresponding part of the mature fly. The terminology used to describe Hox genes can be confusing. They have historical names in the fruit fly (for example, *wltrabithorax*), whereas in mammals they are designated by two competing systems based on lettered (A, B, C, D) or numbered (1, 2, 3, 4) clusters. Loss of Hox genes in fruit flies by mutation or deletion causes the appearance of a normal appendage or body structure at an inappropriate body position. An important example is the *wltrabtithorax* (*wbx*) gene. When Ubx function is lost, the first abdominal segment develops incorrectly, having the structure of the third thoracic segment. Other known homeotic mutations cause the formation of an extra set of wings, or two legs at the position in the head where the antennae are normally found (Fig. 28-42). The Hox genes often span long regions of DNA. The *wbx* gene, for example, is 77,000 bp long. More than 73,000 bp of this gene are in introns, one of which is more than 50,000 bp long. Transcription of the *wbx* gene takes nearly an hour. The delay this imposes on *wbx* gene expression is believed to be a timing mechanism involved in the temporal regulation of subsequent steps in development. Many Hox genes are further regulated by miRNAs encoded by intergenic regions of the Hox gene clusters. All of the Hox gene products are themselves transcription factors that regulate the expression of an array of downstream genes. Identification of these downstream targets is ongoing. Many of the principles of development outlined above apply to other eukaryotes, from nematodes to humans. Some of the regulatory proteins are conserved.

28.3 Regulation of Gene Expression in Eukaryotes 1191

(d) (*bithorax*) in which a segment has developed incorrectly to produce an extra set of wings. For example, the products of the homeobox-containing genes *HOXA7* in mouse and *antennapedia* in fruit fly differ in only one amino acid residue. Of course, although the molecular regulatory mechanisms may be similar, many of the ultimate developmental events are not conserved (humans do not have wings or antennae). The different outcomes are brought about by differences in the downstream target genes controlled by the

Hox genes. The discovery of structural determinants with identifiable molecular functions is the first step in understanding the molecular events underlying development. As more genes and their protein products are discovered, the biochemical side of this vast puzzle will be elucidated in increasingly rich detail. Stem Cells Have Developmental Potential That Can Be Controlled If we can understand development, and the mechanisms of gene regulation behind it, we can control it. An adult human has many different types of tissues. Many of the cells are terminally differentiated and no longer divide. If an organ malfunctions due to disease or a limb is lost in an accident, the tissues are not readily replaced. Most cells, because of the regulatory processes that are in place, or even the loss of some or all genomic DNA, are not easily reprogrammed. Medical science has made organ transplants possible, but organ donors are a limited resource and organ rejection remains a major medical problem. If humans could regenerate their own organs or limbs or nervous tissue, rejection would no longer be an issue. Real cures for kidney failure or neurodegenerative disorders could become reality.

1192 Regulation of Gene Expression The key to tissue regeneration lies in stem cells— cells that have retained the capacity to differentiate into various tissues. In humans, after an egg is fertilized, the first few cell divisions create a ball of totipotent cells (the morula), cells that have the capacity to differentiate individually into any tissue or even into a complete organism (Fig. 28-43). Continued cell division produces a hollow ball, a blastocyst. The outer cells of the blastocyst eventually form the placenta. The inner layers form the germ layers of the developing fetus—the ectoderm, mesoderm, and endoderm. These cells are pluripotent: they can give rise to cells of all three germ layers and can differentiate into many types of tissues. However, they cannot differentiate into a complete organism. Some of these cells are unipotent: they can develop into only one type of cell and/or tissue. It is the pluripotent cells of the blastocyst, the embryonic stem cells, that are currently used in embryonic stem cell research. Stem cells have two functions: to replenish themselves and, at the same time, provide cells that can differentiate. These tasks are accomplished in multiple ways (Fig. 28-44a). All or parts of the stem cell population can, in principle, be involved in replenishment, differentiation, or both. Other types of stem cells can potentially be used for medical benefit. In the adult organism, adult stem cells, as products of additional differentiation, have a more limited potential for further development than do embryonic stem cells. For example, the hematopoietic stem cells of bone marrow can give rise to many types of blood cells and also to cells with the capacity to regenerate bone. They are referred to as multipotent. However, these cells cannot differentiate into a liver or kidney or neuron. Adult stem cells are often said to have a niche, a microenvironment that promotes stem cell maintenance while allowing differentiation of some daughter cells as replacements for cells in the tissue they serve (Fig. 28-44b). Hematopoietic stem cells in the bone marrow occupy a niche in which signaling from

neighboring cells and other cues maintain the stem cell lineage. At the same time, some daughter cells differentiate to provide needed blood cells. Understanding the niche in which stem cells operate, and the signals the niche provides, is essential in efforts to harness the potential of stem cells for tissue regeneration. All stem cells have problems with respect to human medical applications. Adult stem cells have a limited capacity to regenerate tissues, are generally present in small numbers, and are hard to isolate from an adult human. Embryonic stem cells have much greater differentiation potential and can be cultured to generate large numbers of cells. However, their use is accompanied by ethical concerns related to the necessary destruction of human embryos. Identifying a source of plentiful and medically useful stem cells that does not raise concerns remains a major goal of medical research. Our ability to culture stem cells (G.e., maintain them in an undifferentiated state), and to manipulate them to grow and differentiate into particular tissues, is very much a function of our understanding of developmental biology. The identification and culturing of pluripotent

(a) Self-renewal of stem cells. (b) Dividing stem cell. Distal tip of a cell & S. a. —” Differentiated Distal tip 4 < i cell. OO — cell. FIGURE 28-44 Stem cell proliferation versus differentiation and development. Stem cells must strike a balance between self-renewal and differentiation. (a) Some possible cell division patterns that allow for replenishment of stem cells and production of some differentiated cells. Each cell may produce one stem cell and one differentiated cell, or two differentiated cells, or two stem cells in defined parts of the tissue or culture. Or a gradient of growth conditions can be established, with cell fates differing from one end of the gradient to the other. (b) Establishing a developmental niche through stem cell contact with a cell or group of cells. Molecular signals provided by the niche cells (in this case, for plants, a distal tip cell) help orient the mitotic spindle for stem cell division and ensure that one daughter cell retains stem cell properties. stem cells from human blastocysts was reported by James Thomson and colleagues in 1998. This advance led to the long-term availability of established cell lines for research. Thus far, mouse and human embryonic stem cells have been used for most research. Although both types James Thomson 28.3 Regulation of Gene Expression in Eukaryotes 1193 of stem cells are pluripotent, they require very different culture conditions, optimized to allow cell division indefinitely without differentiation. Mouse embryonic stem cells are grown on a layer of gelatin and require the presence of leukemia inhibitory factor (LIF). Human embryonic stem cells are grown on a feeder layer of mouse embryonic fibroblasts and require basic fibroblast growth factor (bFGF or FGF2). The use of a feeder cell layer implies that the mouse cells are providing a diffusible product or some surface signal, not yet known, that is needed by human stem cells to either promote cell division or prevent differentiation. A significant advance, reported in 2007, centers on success in reversing differentiation. In effect, skin cells— first from mice, then from humans—have been reprogrammed to take on the characteristics of pluripotent stem cells. The reprogramming involves manipulations to get the cells to express at least four transcription factors (Oct4, Sox2, Nanog, and Lin28), all of which are known to help maintain the stem cell-like state. Gradual improvements in this technology may make the harvesting of

embryonic stem cells unnecessary and provide a source of stem cells that is genetically matched to a prospective patient. Our discussion of developmental regulation and stem cells brings us full circle, back to a biochemical beginning—both figuratively and literally. Evolution appropriately provides the first and last words of text in this book. If evolution is to generate the kind of changes in an organism that we associate with a different species, it is the developmental program that must be affected. Developmental and evolutionary processes are closely allied, each informing the other (Box 28-1). The continuing study of biochemistry has everything to do with enriching the future of humanity and understanding our origins.

SUMMARY 28.3 Regulation of Gene Expression in Eukaryotes

- > In eukaryotes, positive regulation is more common than negative regulation, and transcription is accompanied by large changes in chromatin structure.
- > Promoters for Pol II typically have a TATA box and Inr sequence, as well as multiple binding sites for transcription activators. The latter sites, sometimes located hundreds or thousands of base pairs away from the TATA box, are called upstream activator sequences in yeast and enhancers in higher eukaryotes.
- > Large complexes of proteins are generally required to regulate transcriptional activity. The effects of transcription activators on Pol II are mediated by coactivator protein complexes such

1194 Regulation of Gene Expression South America has several species of seed-eating finches, commonly called grassquits. About 3 million years ago, a small group of grassquits, of a single species, took flight from the continent's Pacific coast. Perhaps driven by a storm, they lost sight of land and traveled nearly 1,000 km. Small birds such as these might easily have perished on such a journey, but the smallest of chances brought this group to a newly formed volcanic island in an archipelago later to be known as the Galapagos. It was a virgin landscape with untapped plant and insect food sources, and the newly arrived finches survived. Over the years, new islands formed and were colonized by new plants and insects—and by the finches. The birds exploited the new resources on the islands, and groups of birds gradually specialized and diverged into new species. By the time Charles Darwin stepped onto the islands in 1835, there were many different finch species to be found on the various islands of the archipelago, feeding on seeds, fruits, insects, pollen, or even blood. The diversity of living creatures was a source of wonder for humans long before scientists sought to understand its origins. The extraordinary insight handed down to us by Darwin, inspired in part by his encounter with the Galapagos finches, provided a broad explanation for the existence of organisms with a vast array of appearances and characteristics. It also gave rise to many questions about the mechanisms underlying evolution. Answers to those questions have started to appear, first through the study of genomes and nucleic acid metabolism in the last half of the twentieth century, and more recently through an emerging field nicknamed evo-devo—a blend of evolutionary and developmental biology. In its modern synthesis, the theory of evolution has two main elements: mutations in a population generate genetic diversity; natural selection then acts on this diversity to favor individuals with more useful genomic tools and to disfavor others. Mutations occur at significant rates in every individual's genome, in every cell (see Section 8.3 and Fig. 25-20). Advantageous mutations in single-celled organisms or in the as Mediator. The modular structures of the activators have distinct activation and DNAbinding domains. Other protein complexes, including histone acetyltransferases and ATPdependent complexes such as SWI/SNF and NURF, reversibly remodel and modify chromatin structure. > Hormones affect the regulation of gene

expression in one of two ways. Steroid BOX 28-1 Biantle Of Fins, Wings, Beaks, and Things germ line of multicellular organisms can be inherited, and they are more likely to be inherited (that is, are passed on to greater numbers of offspring) if they confer an advantage. It is a straightforward scheme. But many have wondered whether it is enough to explain, say, the many different beak shapes in the Galapagos finches or the diversity of size and shape among mammals. Until recent decades, there were several widely held assumptions about the evolutionary process: that many mutations and new genes would be needed to bring about a new physical structure, that more-complex organisms would have larger genomes, and that very different species would have few genes in common. All of these assumptions were wrong. Modern genomics has revealed that the human genome contains fewer genes than expected—not many more than the fruit fly genome and fewer than some amphibian genomes. The genomes of every mammal, from mouse to human, are surprisingly similar in the number, types, and chromosomal arrangement of genes. Meanwhile, evo-devo is telling us how complex and very different creatures can evolve within these genomic realities. The kinds of mutant organisms shown in Figure 28-42 were studied by the English biologist William Bateson in the late nineteenth century. Bateson used his observations to challenge the Darwinian notion that evolutionary change would have to be gradual. Recent studies of the genes that control organismal development have put an exclamation point on Bateson's ideas. Subtle changes in regulatory patterns during development, reflecting just one or a few mutations, can result in startling physical changes and fuel surprisingly rapid evolution. The Galapagos finches provide a wonderful example of the link between evolution and development. There are at least 14 (some specialists list 15) species of Galapagos finches, distinguished in large measure by their beak structure. The ground finches, for example, have broad, heavy beaks adapted to crushing large, hard seeds. The cactus finches have longer, slender beaks ideal for probing cactus fruits hormones interact directly with intracellular receptors that are DNA-binding regulatory proteins; binding of the hormone has either positive or negative effects on the transcription of genes targeted by the hormone. Nonsteroid hormones bind to cell surface receptors, triggering a signaling pathway that can lead to phosphorylation of a regulatory protein, affecting its activity.

and flowers (Fig. 1). Clifford Tabin and colleagues carefully surveyed a set of genes expressed during avian craniofacial development. They identified a single gene, Bmp4, whose expression level correlated with formation of the more robust beaks of the ground finches. More robust beaks were also formed in chicken embryos when high levels of Bmp4 were artificially expressed in the appropriate tissues, confirming the importance of Bmp4. In a similar study, the formation of long, slender beaks was linked to the expression of calmodulin (see Fig. 12—11) in particular tissues at appropriate developmental stages. Thus, major changes in the shape and function of the beak can be brought about by subtle changes in the expression of just two genes involved in developmental regulation. Very few mutations are required, and the needed mutations affect regulation. New genes are not required. The system of regulatory genes that guides development is remarkably conserved among all vertebrates. Elevated expression of Bmp4 in the right tissue at the right time leads to more robust jaw parts in zebrafish. The same gene plays a key role in tooth development.

FIGURE 1 Evolution of new beak structures to exploit new food sources. In the Galapagos finches, the different beak structures of the cactus finch and the large ground finch, which feed on different, RNA-mediated regulation plays an important role in eukaryotic gene expression, with the range of known mechanisms expanding. Development of a multicellular organism presents the most complex regulatory challenge. The fate of cells in the early embryo is determined by establishment of anterior-posterior and dorsalventral gradients of proteins that act as transcription activators or translational repressors. Probing cactus flowers/fruit High [CaM]: elongated beak Low [Bmp4]: low beak depth/width

28.3 Regulation of Gene Expression in Eukaryotes

11.95 development in mammals. The development of eyes is triggered by the expression of a single gene, Pax6, in fruit flies and in mammals. The mouse Pax6 gene will trigger the development of fruit fly eyes in the fruit fly, and the fruit fly Pax6 gene will trigger the development of mouse eyes in the mouse. In each organism, these genes are part of the much larger regulatory cascade that ultimately creates the correct structures in the correct locations in each organism. The cascade is ancient; for example, the Hox genes (described in the text) have been part of the developmental

program of multicellular eukaryotes for more than 500 million years. Subtle changes in the cascade can have large effects on development, and thus on the ultimate appearance, of the organism. These same subtle changes can fuel remarkably rapid evolution. For example, the 400 to 500 described species of cichlids (spiny-finned fish) in Lake Malawi and Lake Victoria on the African continent are all derived from one or a few populations that colonized each lake in the past 100,000 to 200,000 years. The Galapagos finches simply followed a path of evolution and change that living creatures have been traveling for billions of years. Mixed diet of seeds and insects

Ancestor Low [CaM]: short beak Low [Bmp4]: low beak depth/width a Crushing hard/large seeds Early/high [Bmp4]: high beak depth/width specialized food sources, were produced to a large extent by a few mutations that altered the timing and level of expression of just two genes: those encoding calmodulin (CaM) and Bmp4. regulating the genes required for the development of structures appropriate to a particular part of the organism. Sets of regulatory genes operate in temporal and spatial succession, transforming given areas of an egg cell into predictable structures in the adult organism. > The differentiation of stem cells into functional tissues can be controlled by extracellular signals and conditions.

Problems 1. Effect of mRNA and Protein Stability on Regulation E. coli cells are growing in a medium with glucose as the sole carbon source. Tryptophan is suddenly added. The cells continue to grow, and divide every 30 min. Describe (qualitatively) how the amount of tryptophan synthase activity in the cells changes with time under the following conditions: (a) The trp mRNA is stable (degraded

slowly over many hours).

(b) The *trp* mRNA is degraded rapidly, but tryptophan synthase is stable. (c) The *trp* mRNA and tryptophan synthase are both degraded rapidly.

2. The Lactose Operon A researcher engineers a *lac* operon on a plasmid but inactivates all parts of the *lac* operator (*lacO*) and the *lac* promoter, replacing them with the binding site for the LexA repressor (which acts in the SOS response) and a promoter regulated by LexA. The plasmid is introduced into *E. coli* cells that have a *lac* operon with an inactive *lacZ* gene. Under what conditions will these transformed cells produce B-galactosidase?

3. Negative Regulation Describe the probable effects on gene expression in the *lac* operon of a mutation in (a) the *lac* operator that deletes most of *O*₄, (b) the *lacI* gene that inactivates the repressor, and (c) the promoter that alters the region around position — 10.

4. Specific DNA Binding by Regulatory Proteins A typical bacterial repressor protein discriminates between its specific DNA-binding site (operator) and nonspecific DNA by a factor of 10^4 to 10^6 . About 10 molecules of repressor per cell are sufficient to ensure a high level of repression. Assume that a very similar repressor existed in a human cell, with a similar specificity for its binding site. How many copies of the repressor would be required to elicit a level of repression similar to that in the bacterial cell? (Hint: The *E. coli* genome contains about 4.6 million bp; the human haploid genome has about 3.2 billion bp.)

5. Repressor Concentration in *E. coli* The dissociation constant for a particular repressor-operator complex is very low, about 10^{-7} M. An *E. coli* cell (volume 2×10^{-12} mL) contains 10 copies of the repressor. Calculate the cellular concentration of the repressor protein. How does this value compare with the dissociation constant of the repressor-operator complex? What is the significance of this answer?

6. Catabolite Repression *E. coli* cells are growing in a medium containing lactose but no glucose. Indicate whether each of the following changes or conditions would increase, decrease, or not change the expression of the *lac* operon. It may be helpful to draw a model depicting what is happening in each situation. (a) Addition of a high concentration of glucose (b) A mutation that prevents dissociation of the Lac repressor from the operator (c) A mutation that completely inactivates B-galactosidase (d) A mutation that completely inactivates galactoside permease (e) A mutation that prevents binding of CRP to its binding site near the *lac*

promoter 7. Transcription Attenuation How would transcription of the *E. coli* trp operon be affected by the following manipulations of the leader region of the trp mRNA? (a) Increasing the distance (number of bases) between the leader peptide gene and sequence 2 (b) Increasing the distance between sequences 2 and 3 (c) Removing sequence 4 (d) Changing the two Trp codons in the leader peptide gene to His codons Problems 1197 (e) Eliminating the ribosome-binding site for the gene that encodes the leader peptide (f) Changing several nucleotides in sequence 3 so that it can base-pair with sequence 4 but not with sequence 2 8. Repressors and Repression How would the SOS response in *E. coli* be affected by a mutation in the *lexA* gene that prevented autocatalytic cleavage of the LexA protein? 9. Regulation by Recombination In the phase variation system of *Salmonella*, what would happen to the cell if the *Hin* recombinase became more active and promoted recombination (DNA inversion) several times in each cell generation? 10. Initiation of Transcription in Eukaryotes A new RNA polymerase activity is discovered in crude extracts of cells derived from an exotic fungus. The RNA polymerase initiates transcription only from a single, highly specialized promoter. As the polymerase is purified its activity declines, and the purified enzyme is completely inactive unless crude extract is added to the reaction mixture. Suggest an explanation for these observations. 11. Functional Domains in Regulatory Proteins A biochemist replaces the DNA-binding domain of the yeast Gal4 protein with the DNA-binding domain from the Lac repressor and finds that the engineered protein no longer regulates transcription of the GAL genes in yeast. Draw a diagram of the different functional domains you would expect to find in the Gal4 protein and in the engineered protein. Why does the engineered protein no longer regulate transcription of the GAL genes? What might be done to the DNA-binding site recognized by this chimeric protein to make it functional in activating transcription of GAL genes? 12. Nucleosome Modification during Transcriptional Activation To prepare genomic regions for transcription, certain histones in the resident nucleosomes are acetylated and methylated at specific locations. Once transcription is no longer needed, these modifications need to be reversed. In mammals, the methylation of Arg residues in histones is reversed by peptidylarginine deiminases (PADIs). The reaction promoted by these enzymes does not yield unmethylated

arginine. Instead, it produces citrulline residues in the histone. What is the other product of the reaction? Suggest a mechanism for this reaction.

13. Inheritance Mechanisms in Development A *Drosophila* egg that is *bcd* / *bcd* may develop normally, but the adult fruit fly will not be able to produce viable offspring. Explain.

Data Analysis Problem 14. Engineering a Genetic Toggle Switch in *Escherichia coli* Gene regulation is often described as an “on or off” phenomenon—a gene is either fully expressed or not expressed at all. In fact, repression and activation of a gene involve ligand-binding reactions, so genes can show intermediate levels of expression when intermediate levels of regulatory molecules are present. For example, for the *E. coli* lac operon, consider the binding equilibrium of the Lac repressor, operator

1198 Regulation of Gene Expression DNA, and inducer (see Fig. 28-8). Although this is a complex, cooperative process, it can be approximately modeled by the following reaction (R is repressor; IPTG is the inducer isopropyl-B-b-thiogalactoside): $K_s = 10^7 \text{ u}$ $R + \text{IPTG} \rightleftharpoons R \cdot \text{IPTG}$ Free repressor, R, binds to the operator and prevents transcription of the lac operon; the $R \cdot \text{IPTG}$ complex does not bind to the operator and thus transcription of the lac operon can proceed. (a) Using Equation 5-8, we can calculate the relative expression level of the proteins of the lac operon as a function of [IPTG]. Use this calculation to determine over what range of [IPTG] the expression level would vary from 10% to 90%. (b) Describe qualitatively the level of lac operon proteins present in an E. coli cell before, during, and after induction with IPTG. You need not give the amounts at exact times—just indicate the general trends. Gardner, Cantor, and Collins (2000) set out to make a “genetic toggle switch”—a gene-regulatory system with two key characteristics of a light switch. (A) It has only two states: it is either fully on or fully off; it is not a dimmer switch. In biochemical terms, the target gene or gene system (operon) is either fully expressed or not expressed at all; it cannot be expressed at an intermediate level. (B) Both states are stable: although you must use a finger to flip the light switch from one state to the other, once you have flipped it and removed your finger, the switch stays in that state. In biochemical terms, exposure to an inducer or some other signal changes the expression state of the gene or operon, and it remains in that state once the signal is removed. (c) Explain how the lac operon lacks both characteristics A and B. To make their “toggle switch,” Gardner and coworkers constructed a plasmid from the following components: OP_{lac}, The operator-promoter region of the E. coli lac operon; OP_ϕ, The operator-promoter region of a phage; lacI, The gene encoding the lac repressor protein, LacI. In the absence of IPTG, this protein strongly represses OP_{lac}; in the presence of IPTG, it allows full expression from OP_ϕ. rep⁺, The gene encoding a temperature-sensitive mutant A repressor protein, repress⁺. At 37°C this protein strongly represses OP_{lac}; at 42°C it allows full expression from OP_ϕ. GFP, The gene for green fluorescent protein (GFP), a highly fluorescent reporter protein (see Fig. 9-16). T, Transcription terminator. The investigators arranged these components (see figure below) so that the two promoters were

reciprocally repressed: OP, controlled expression of rep", and OP, controlled expression of lacI. The state of this system was reported by the expression level of GFP, which was also under the control of OPhac. (d) The constructed system has two states: GFP-on (high level of expression) and GFP-off (low level of expression). For each state, describe which proteins are present and which promoters are being expressed. lac repressor ϕ A repressor D GFP mRNA (e) Treatment with IPTG would be expected to toggle the system from one state to the other. From which state to which? Explain your reasoning. (f) Treatment with heat (42°C) would be expected to toggle the system from one state to the other. From which state to which? Explain your reasoning. (g) Why would this plasmid be expected to have characteristics A and B as described above? To confirm that their construct did indeed exhibit these characteristics, Gardner and colleagues first showed that, once switched, the GFP expression level (high or low) was stable for long periods of time (characteristic B). Next, they measured GFP level at different concentrations of the inducer IPTG, with the following results.

[IPTG]	Normalized GFP expression
1.0	0.8
0.6	0.4
0.4	0.2
0.2	10 ⁻⁶
10 ⁻⁶	10 ⁻⁵
X	10 ⁻⁴
10 ⁻³	10 ⁻²

(m) They noticed that the average GFP expression level was intermediate at concentration X of IPTG. However, when they measured the GFP expression level in individual cells at [IPTG] = X, they found either a high level or a low level of GFP—no cells showed an intermediate level. (h) Explain how this finding demonstrates that the system has characteristic A. What is happening to cause the bimodal distribution of expression levels at [IPTG] = X? Reference Gardner, T.S., Cantor, C.R., & Collins, J.J. (2000) Construction of a genetic toggle switch in *Escherichia coli*. *Nature* 403, 339-342.

Abbreviated Solutions to Problems Fuller solutions to all chapter problems are published in the Absolute Ultimate Study Guide to Accompany Principles of Biochemistry. For all numerical problems, answers are expressed with the correct number of significant figures.

Chapter 1

1. (a) Diameter of magnified cell = 500 μm (b) 2.7×10^7 actin molecules (c) 36,000 mitochondria (d) 3.9×10^{10} glucose molecules (e) 50 glucose molecules per hexokinase molecule
2. (a) 1×10^{-11} g = 1 pg (b) 10% (c) 5%

4. (a) Metabolic rate is limited by diffusion, which is limited by surface area. (b) 12 μm^2 for the bacterium; 0.04 μm^2 for the amoeba; surface-to-volume ratio 300 times higher in the bacterium.
5. 2×10^6 s (about 23 days)
6. The vitamin molecules from the two sources are identical; the body cannot distinguish the source; only associated impurities might vary with the source.
 - (a) H (b) $\text{T} + \text{le m H H H}-\text{C}-\text{OH}$ Hydroxyls Amino Hydroxyl "PN | H (c) o (d) COO Carboxyl I | $\text{HO}-\text{P}-\text{O}$ Phosphoryl Amino $\text{D H}^\circ =$ Hydroxyl A $> -\text{EE CH}$; H Carboxyl Methyl (e) - (f) a Carboxyl a Aldehyde l CH, $\text{H}-\text{C}-\text{NH}$; Amino CH, Hydroxyl $\text{HO}-\text{C}-\text{H NH}$ Amido $\text{H}-\text{C}-\text{OH C}=\text{O H}-\text{C}-\text{OH}$ Hydroxyls $\text{H}-\text{C}-\text{OH}$ Hydroxyl CHOH Methyl $\text{H}_3\text{C}-\text{C}-\text{CH}_3$ Methyl CH, OH Hydroxyl not ew ti $\text{HO} [\setminus \text{i CH}, -\text{N j} - \text{H CH}, \text{HO CH},$ The two enantiomers have different interactions with a chiral biological "receptor" (a protein).
9. (a) Only the amino acids have amino groups; separation could be based on the charge or binding affinity of these groups. Fatty acids are less soluble in water than amino acids, and the two types of 10. 11. 12. 13. 14. molecules also differ in size and shape—either of these property differences could be the basis for separation. (b) Glucose is a smaller molecule than a nucleotide; separation could be based on size. The nitrogenous base and/or the phosphate group also endows nucleotides with characteristics (solubility, charge) that could be used for separation from glucose. It is improbable that silicon could serve as the central organizing element for life, especially in an Os -containing atmosphere such as that of Earth. Long chains of silicon atoms are not readily synthesized; the polymeric macromolecules necessary for more complex functions would not readily form. Oxygen disrupts bonds between silicon atoms, and silicon—oxygen bonds are extremely stable and difficult to break, preventing the breaking

and making of bonds that is essential to life processes. Only one enantiomer of the drug was physiologically active. Dexedrine consisted of the single enantiomer; Benzedrine consisted of a racemic mixture. (a) 3 Phosphoric acid groups; a-D-ribose; guanine (b) Choline; phosphoric acid; glycerol; oleic acid; palmitic acid (ec) Tyrosine; 2 glycines; phenylalanine; methionine (a) CH₂O; C₃H₇O₃ (b) mm How ow —C—C H—C—C —C—C \ X \ i c—OH H₄ C—OH i c-on HO HO 1 2 3 OH oH OH H H OH o 7 | Y | | 4 HO—C—C HO—C—C H—C—C—C S | NS i [| Š H CH H ,C—oH nH OH H 4 5 6 HOH o HO OH o H OH o | | 4 | | ¢ | | 4 H—C—C—C H—C—C—€ H₀₀₀, HH H H H 'i H oH H 7 8 9 2 a We H—C—C—C H—C—C—C—H H—C—C—C—H HOH H H H H OH 10 11 12 Ce) X contains a chiral center; eliminates all but 6 and 8. (d) X contains an acidic functional group; eliminates 8; structure 6 is consistent with all data. (e) Structure 6; we cannot distinguish between the two possible enantiomers. The compound shown is (?)-propranolol; the carbon bearing the hydroxyl group is the chiral carbon. (S)-Propranolol has the structure: AS-1

AS-2 Abbreviated Solutions to Problems 15. 16. | \ D-Tryptophan The compound shown is (S,S)-methylphenidate. (R,R)-methylphenidate has the structure: The chiral carbons are indicated with asterisks. (a) A more negative AG° corresponds to a larger Keq for the binding reaction, so the equilibrium is shifted more toward products and tighter binding—and thus greater sweetness and higher MRS. (b) Animal-based sweetness assays are timeconsuming. A computer program to predict sweetness, even if not always completely accurate, would allow chemists to design effective sweeteners much faster. Candidate molecules could then be tested in the conventional assay. (c) The range 0.25 to 0.4 nm corresponds to about 1.5 to 2.5 single-bond lengths. The figure below can be used to construct an approximate ruler; any atoms in the light red rectangle are between 0.25 and 0.4 nm from the origin of the ruler. E There are many possible AH-B groups in the molecules; a few are shown here. H OH HO HO H H } i o HO OH So OH H OH |, Deoxysucrose H OH HO HO HO “ H (0) | Ho és OH `o on OH H Sucrose NHp N H CH; Saccharin Aspartame 6-Chloro-p-tryptophan Alitame H < N ” OH ian CH3 Neotame (0) H O wr" i S\$ OX OH NH o7~o Sucronic acid Tetrabromosucrose (d) First, each molecule has multiple AH-B groups, so it is difficult to know which is the important one. Second, because the AH-B motif is very simple, many nonsweet molecules will have this group. (e) Sucrose and deoxysucrose. Deoxysucrose lacks one of the AH-B groups present in sucrose and has a slightly lower MRS than sucrose—as is expected if the AH-B groups are important for sweetness. (f) There are many such examples; here are a few: (1) b-Tryptophan and 6-chloro-btryptophan have the same AH-B group but very different MRS values. (2) Aspartame and neotame have the same AH-B groups but very different MRS values. (3) Neotame has two AH-B groups and alitame has three, yet neotame is more than five times sweeter than alitame. (4) Bromine is less electronegative than oxygen and thus is expected to weaken an AH-B group, yet tetrabromosucrose is much sweeter than sucrose. (g) Given enough “tweaking” of parameters, any model can be made to fit a defined dataset. Because the objective was to create a model to predict AG° for molecules not tested in vivo, the researchers needed to show that the model worked well for molecules it had not been trained on. The degree of inaccuracy with the test set could give researchers

an idea of how the model would behave for novel molecules. (h) MRS is related to K_{eq} , which is related exponentially to ΔG° , so adding a constant amount to ΔG° multiplies the MRS by a constant amount. Based on the values given with the structures, a change in ΔG° of 1.3 kcal/mol corresponds to a 10-fold change in MRS.

25. Mix 150 mL of 0.10 M sodium acetate and 850 mL of 0.10 M acetic acid. 26. Acetic acid; its pK_a is closest to the desired pH. 27. (a) 4.6 (b) 0.1 pH unit (c) 4 pH units 28. 4.3 29. 0.13 M acetate and 0.07 M acetic acid 30. 1.7 31.7 32. (a) ee 7: i a ae S CH_3CH_2 ; Fully protonated Fully deprotonated (b) fully protonated (c) zwitterion (d) zwitterion (e) fully deprotonated 33. (a) Blood pH is controlled by the carbon dioxide-bicarbonate buffer system, $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$. During hypoventilation, $[CO_2]$ increases in the lungs and arterial blood, driving the equilibrium to the right, raising $[H^+]$ and lowering pH. (b) During hyperventilation, $[CO_2]$ decreases in the lungs and arterial blood, reducing $[H^+]$ and increasing pH above the normal 7.4 value. (c) Lactate is a moderately strong acid, completely dissociating under physiological conditions and thus lowering the pH of blood and muscle tissue. Hyperventilation removes H^+ , raising the pH of blood and tissues in anticipation of the acid buildup. 34. 7.4 35. Dissolving more CO_2 in the blood increases $[H^+]$ in blood and extracellular fluids, lowering pH: $CO_2(d) + H_2O \rightleftharpoons H^+ + HCO_3^-$; 36. (a) Use the substance in its surfactant form to emulsify the spilled oil, collect the emulsified oil, then switch to the nonsurfactant form. The oil and water will separate and the oil can be collected for further use. (b) The equilibrium lies strongly to the right. The stronger acid (lower pK_a), H_2CO_3 , donates a proton to the conjugate base of the weaker acid (higher pK_a), amidine. (c) The strength of a surfactant depends on the hydrophilicity of its head groups: the more hydrophilic, the more powerful the surfactant. The amidinium form of s-surf is much more hydrophilic than the amidine form, so it is a more powerful surfactant. (d) Point A: amidinium; the CO_2 has had plenty of time to react with the amidine to produce the amidinium form. Point B: amidine; Ar has removed CO_2 from the solution, leaving the amidine form. (e) The conductivity rises as uncharged amidine reacts with CO_2 to produce the charged amidinium form. (f) The conductivity falls as Ar removes CO_2 , shifting the equilibrium to the uncharged amidine form. (g) Treat s-surf with CO_2 to produce the surfactant amidinium form and use this to emulsify the spill. Treat the emulsion with Ar to remove the CO_2 ; and produce the nonsurfactant amidine form. The oil will separate from the water and can be recovered. Chapter 3 1. I; determine the absolute configuration at the α carbon and compare it with D- and

(a) Structure at pH 7: o o O EE oe pK , = 8.03 pK , = 3.39 (b) Electrostatic interaction between the carboxylate anion and the protonated amino group of the alanine zwitterion favorably affects the ionization of the carboxyl group. This favorable electrostatic interaction decreases as the length of the poly(Ala) increases, resulting in an increase in pK . (c) Ionization of the protonated amino group destroys the favorable electrostatic interaction noted in (b). With increasing distance between the charged groups, removal of the proton from the amino group in poly(Ala) becomes easier and thus pK is lower. The intramolecular effects of the amide (peptide bond) linkages keep pK values lower than they would be for an alkyl-substituted amine. 8. 75,000 9. (a) 32,000. The elements of water are lost when a peptide bond forms, so the molecular weight of a Trp residue is not the same as the molecular weight of free tryptophan. (b) 2

(a) Y (1), F (7), and R (9) (b) Positions 4 and 9; K (Lys) is more common at 4, R (Arg) is invariant at 9 (c) Positions 5 and 10; E (Glu) is more common at both positions (d) Position 2; S (Ser) (a) peptide 2 (b) peptide 1 (c) peptide 2 (d) peptide 3 (a) Any linear polypeptide chain has only two kinds of free amino groups: a single α -amino group at the amino terminus, and an ω -amino group on each Lys residue present. These amino groups react with FDNB to form a DNP-amino acid derivative. Insulin gave two different α -amino-DNP derivatives, suggesting that it has two amino termini and thus two polypeptide chains—one with an amino-terminal Gly and the other with an amino-terminal Phe. Because the DNP-lysine product is ϵ -DNP-lysine, the Lys is not at an amino terminus. (b) Yes. The A chain has amino-terminal Gly; the B chain has amino-terminal Phe; and (nonterminal) residue 29 in the B chain is Lys. (c) Phe—Val—Asp—Glu-. Peptide B1 shows that the amino-terminal residue is Phe. Peptide B2 also includes Val, but since no DNP-Val is formed, Val is not at the amino terminus; it must be on the carboxyl side of Phe. Thus the sequence of B2 is DNP-Phe—Val. Similarly, the sequence of B3 must be DNP-Phe—Val—Asp, and the sequence of the A chain must begin Phe—Val—Asp—Glu-. (d) No. The known amino-terminal

sequence of the A chain is Phe-Val-Asn-Gln-. The Asn and Gln appear in Sanger's analysis as Asp and Glu because the vigorous hydrolysis in step 7 hydrolyzed the amide bonds in Asn and Gln (as well as the peptide bonds), forming Asp and Glu. Sanger et al. could not distinguish Asp from Asn or Glu from Gln at this stage in their analysis. (e) The sequence exactly matches that in Fig. 3-24. Each peptide in the table gives specific information about which Asx residues are Asn or Asp and which Glx residues are Glu or Gln. Ac1: residues 20-21. This is the only Cys—Asx sequence in the A chain; there is ~1 amido group in this peptide, so it must be Cys—Asn: N-Gly—Ile—Val—Glx—Glx—Cys—Cys—Ala—Ser—Val 1 5 10 Cys—Ser—Leu—Tyr—Glx—Leu—Glx—Asx—Tyr—Cys—Asn—C 15 20 Ap15: residues 14-15-16. Chapter 4 1. (a) Shorter bonds have a higher bond order (are multiple rather than single) and are stronger. The peptide C—N bond is stronger than a single bond and is midway between a single and a double bond in character. (b) Rotation about the peptide bond is difficult at physiological temperatures because of its partial double-bond character. 2. (a) The principal structural units in the wool fiber polypeptide (a-keratin) are successive turns of the α helix, at 5.4 Å intervals; coiled coils produce the 5.2 Å spacing. Steaming and

stretching the fiber yields an extended polypeptide chain with the B conformation, with a distance between adjacent R groups of about 7.0 Å. As the polypeptide reassumes an α -helical structure, the fiber shortens. (b) Processed wool shrinks when polypeptide chains are converted from an extended β conformation to the native α -helical conformation in the presence of moist heat. The structure of silk—sheets, with their small, closely packed amino acid side chains—is more stable than that of wool. 3. ~ 42 peptide bonds per second 4. At pH > 6 , the carboxyl groups of poly(Glu) are deprotonated; repulsion among negatively charged carboxylate groups leads to unfolding. Similarly, at pH 7, the amino groups of poly(Lys) are protonated; repulsion among these positively charged groups also leads to unfolding. 5. (a) Disulfide bonds are covalent bonds, which are much stronger than the noncovalent interactions that stabilize most proteins. They cross-link protein chains, increasing their stiffness, mechanical strength, and hardness. (b) Cystine residues (disulfide bonds) prevent the complete unfolding of the protein.

«1 R=) 10. 11. 12. 13. 14. 15. 16. . \$ = (D and y = (e). .
 (a) Bends are most likely at residues 7 and 19; Pro residues in the cis configuration accommodate turns well. (b) The Cys residues at positions 13 and 24 can form disulfide bonds. (c) External surface: polar and charged residues (Asp, Gln, Lys); interior: nonpolar and aliphatic residues (Ala, Ile); Thr, though polar, has a hydropathy index near zero and thus can be found either on the external surface or in the interior of the protein. . 30 amino acid residues; 0.87 . Myoglobin is all three. The folded structure, the “globin fold,” is a motif found in all globins. The polypeptide folds into a single domain, which for this protein represents the entire threedimensional structure. Protein (a), a B barrel, is described by Ramachandran plot (c), which shows most of the allowable conformations in the upper left quadrant where the bond angles characteristic of the B conformation are concentrated; (b), a series of æ helices, is described by plot (d), where most of the allowable conformations are in the lower left quadrant. The bacterial enzyme is a collagenase; it destroys the connective tissue barrier of the host, allowing the bacterium to invade the tissues. Bacteria do not contain collagen. (a) The number of moles of DNP-valine formed per mole of protein equals the number of amino termini and thus the number of polypeptide chains. (b) 4 (e) Different chains would probably run as discrete bands on an SDS polyacrylamide gel. (a); it has more amino acid residues that favor a-helical structure (see Table 4-1). (a) Aromatic residues seem to play an important role in stabilizing amyloid fibrils. Thus, molecules with aromatic substituents may inhibit amyloid formation by interfering with the stacking or association of the aromatic side chains. (b) Amyloid is formed in the pancreas in association with type 2 diabetes, as it is in the brain in Alzheimer disease. Although the amyloid fibrils in the two diseases involve different proteins, the fundamental structure of the amyloid is similar and similarly stabilized in both, and so they are potential targets for similar drugs designed to disrupt this structure. (a) NF«B transcription factor, also called RelA transforming factor. (b) No. You will obtain similar results, but with additional related proteins listed. (c) The protein has two subunits. There are multiple variants of the subunits, with the best characterized being 50, 52, or 65 kDa. These pair with each other to form a variety of homodimers and heterodimers. The structures

of a number of different variants can be found in the PDB. (d) The NF κ B transcription factor is a dimeric protein that binds specific DNA sequences, enhancing transcription of nearby genes. One such gene is the immunoglobulin κ light chain, from which the transcription factor gets its name. (a) Aba is a suitable replacement because Aba and Cys have side chains of approximately the same size and are similarly hydrophobic. However, Aba cannot form disulfide bonds, so it will not be a suitable replacement if these are required. (b) There are many important differences between the synthesized protein and HIV protease produced by a human cell, any of which could result in an inactive synthetic enzyme: (1) Although Aba and Cys have similar size and hydrophobicity, Aba may not be similar enough for the protein to fold properly. (2) HIV protease may require disulfide bonds for proper functioning. (8) Many proteins synthesized by ribosomes fold as they are produced; the protein in this study folded only after the chain was complete. (4) Proteins synthesized by ribosomes may interact with the ribosomes as they fold; this is not possible for the protein in the study. (5) Cytosol is a more complex solution than the buffer used in the study; some proteins may require specific, unknown proteins for proper folding. (6) Proteins synthesized in cells AS-5 Abbreviated Solutions to Problems often require chaperones for proper folding; these are not present in the study buffer. (7) In cells, HIV protease is synthesized as part of a larger chain that is then proteolytically processed; the protein in the study was synthesized as a single molecule. (c) Because the enzyme is functional with Aba substituted for Cys, disulfide bonds do not play an important role in the structure of HIV protease. (d) Model 1: It would fold like the L-protease. Argument for: The covalent structure is the same (except for chirality), so it should fold like the L-protease. Argument against: Chirality is not a trivial detail; three-dimensional shape is a key feature of biological molecules. The synthetic enzyme will not fold like the L-protease. Model 2: It would fold to the mirror image of the L-protease. For: Because the individual components are mirror images of those in the biological protein, it will fold in the mirror-image shape. Against: The interactions involved in protein folding are very complex, so the synthetic protein will most likely fold in another form. Model 3: It would fold to something else. For: The interactions involved in protein folding are very complex, so the synthetic protein will most likely fold in another form. Against:

Because the individual components are mirror images of those in the biological protein, it will fold in the mirror-image shape. (e) Model 1. The enzyme is active, but with the enantiomeric form of the biological substrate, and it is inhibited by the enantiomeric form of the biological inhibitor. This is consistent with the b-protease being the mirror image of the L-protease. (ff) Evans blue is achiral; it binds to both forms of the enzyme. (g) No. Because proteases contain only L-amino acids and recognize only L-peptides, chymotrypsin would not digest the D-protease. (h) Not necessarily. Depending on the individual enzyme, any of the problems listed in (b) could result in an inactive enzyme. Chapter 5 1. Protein B has a higher affinity for ligand X; it will be half-saturated at a much lower concentration of X than will protein A. Protein A has $K_d = 10^{-6} \text{ M}$; protein B has $K_d = 10^{-7} \text{ M}$. . (a), (b), and (c) all have $n_H < 1.0$. Apparent negative cooperativity in ligand binding can be caused by the presence of two or more types of ligand-binding sites with different affinities for the ligand on the same or different proteins in the same solution. Apparent negative cooperativity is also commonly observed in heterogeneous protein preparations. There are few well-documented cases of true negative cooperativity. . (a) decreases (b) increases (c) decreases (d) increases 4. $K_a = 89 \times 10^{-6} \text{ M}$. . (a) 0.5 nM (shortcut: the K_d is equivalent to the ligand concentration where $\theta = 0.5$). (b) Protein 2 has the highest affinity, as it has the lowest K_d . . The cooperative behavior of hemoglobin arises from subunit interactions. . (a) The observation that hemoglobin A (HbA; maternal) is about 60% saturated when the pO_2 is 4 kPa, whereas hemoglobin F (HbF; fetal) is more than 90% saturated under the same physiological conditions, indicates that HbF has a higher O_2 affinity than HbA. (b) The higher O_2 affinity of HbF ensures that oxygen will flow from maternal blood to fetal blood in the placenta. Fetal blood approaches full saturation where the O_2 affinity of HbA is low. (c) The observation that the O_2 -saturation curve of HbA undergoes a larger shift on BPG binding than that of HbF suggests that HbA binds BPG more tightly than does HbF. Differential binding of BPG to the two hemoglobins may determine the difference in their O_2 affinities. . (a) Hb Memphis (b) HbS, Hb Milwaukee, Hb Providence, possibly Hb Cowtown (c) Hb Providence . More tightly. An inability to form tetramers would limit the cooperativity of these variants, and the binding curve would become more hyperbolic. Also, the BPG-binding site would

be

AS-6 Abbreviated Solutions to Problems 10. 11. 12. 13. 15. 16. 17. disrupted. Oxygen binding would probably be tighter, because the default state in the absence of bound BPG is the tightbinding R state. (a) $1 \times 10^8 \text{ m}$ (b) $5 \times 10^0 \text{ m}$ (c) $8 \times 10^0 \text{ m}$ (d) $2 \times 10^7 \text{ m}$. Note that a rearrangement of Eqn 5-8 gives $[L] = 0K_a/(1 - 0)$. The epitope is likely to be a structure that is buried when G-actin polymerizes to F-actin. Many pathogens, including HIV, have mechanisms by which they can repeatedly alter the surface proteins to which immune system components initially bind. Thus the host organism regularly faces new antigens and requires time to mount an immune response to each one. As the immune system responds to one variant, new variants are created. Binding of ATP to myosin triggers dissociation of myosin from the actin thin filament. In the absence of ATP, actin and myosin bind tightly to each other. (a) (b) (c) (d) (a) Chain L is the light chain and chain H is the heavy chain of the Fab fragment of this antibody molecule. Chain Y is lysozyme. (b) 8 structures are predominant in the variable and constant regions of the fragment. (c) Fab heavy-chain fragment, 218 amino acid residues; light-chain fragment, 214; lysozyme, 129. Less than 15% of the lysozyme molecule is in contact with the Fab fragment. (d) In the H chain, residues that seem to be in contact with lysozyme include Gly⁴¹, Tyr⁵⁰, Arg⁵², Asp⁵³, and Tyr⁵⁴. In the L chain the residues that seem to be in contact with lysozyme include Tyr³⁴, Tyr³⁵, Tyr³⁶, and Trp³⁷. In lysozyme, residues Asn⁴⁴, Gly⁴⁵, Tyr⁴⁶, Ser⁴⁷, Lys⁴⁸, Gly⁴⁹, Thr⁵⁰, Asp⁵¹, Gin⁵² and Arg⁵³ seem to be situated at the antigen-antibody interface. Not all these residues are adjacent in the primary structure. Folding of the polypeptide chain into higher levels of structure brings the nonconsecutive residues together to form the antigen-binding site. (a) The protein with a K_d of $5 \text{ } \mu\text{M}$ will have the highest affinity for ligand L. When the K_d is $10 \text{ } \mu\text{M}$, doubling $[L]$ from 0.2 to $0.4 \text{ } \mu\text{M}$ (values well below the K_d) will nearly double θ (the actual increase factor is 1.96). This is a property of the hyperbolic curve; at low ligand concentrations, θ is an almost linear function of $[L]$. On the other hand, doubling $[L]$ from 40 to $80 \text{ } \mu\text{M}$ (well above the K_d , where the binding curve is approaching its asymptotic limit) will increase θ by a factor of only 1.1. The increase factors are identical for the curves generated from Eqn 5-11. (b) $\theta = 0.998$. (c) A variety of answers will be obtained,

depending on the values entered for the different parameters. (a) The drawing is not to scale; any given cell would have many more myosin molecules on its surface. (b) ATP is needed to provide the chemical energy to drive the motion (see Chapter 13). (c) An antibody that bound to the myosin tail, the actin-binding site, would block actin binding and prevent movement. An antibody that bound to actin would also prevent actin-myosin interaction and thus movement. (d) There are two possible explanations: (1) Trypsin cleaves only at Lys and Arg residues (see Table 3-6) so would not cleave at many sites in the protein. (2) Not all Arg or Lys residues are equally accessible to trypsin; the most-exposed sites would be cleaved first. (e) The S1 model. The hinge model predicts that bead-antibody-HMM complexes (with the hinge) would move, but bead-antibody-SHMM complexes (no hinge) would not. The S1 model predicts that because both complexes include S1, both would move. The finding that the beads move with SHMM (no hinge) is consistent only with the S1 model. (f) With fewer myosin molecules bound, the beads could temporarily fall off the actin as a myosin let go of it. The beads would then move more slowly, as time is required for a second myosin to bind. At higher myosin density, as one myosin lets go, another quickly binds, leading to faster motion. (g) Above a certain density, what limits the rate of movement is the intrinsic speed with which myosin molecules move the beads. The myosin molecules are moving at a maximum rate and adding more will not increase speed. (h) Because the force is produced in the S1 head, damaging the S1 head would probably inactivate the resulting molecule, and SHMM would be incapable of producing movement. (i) The S1 head must be held together by noncovalent interactions that are strong enough to retain the active shape of the molecule.

Chapter 6 1 11. 12. 13. 14. 15. 16. 17. . The activity of the enzyme that converts sugar to starch is destroyed by heat denaturation. 24×10^6 M . 9.5×10^6 years . The enzyme-substrate complex is more stable than the enzyme alone. . (a) 190 Å (b) Three-dimensional folding of the enzyme brings the amino acid residues into proximity. . The reaction rate can be measured by following the decrease in absorption by NADH (at 340 nm) as the reaction proceeds. Determine the K_m value; using substrate concentrations well above the K_m , measure initial rate (rate of NADH disappearance with time, measured spectrophotometrically) at several known enzyme concentrations, and make a plot of initial

rate versus concentration of enzyme. The plot should be linear, with a slope that provides a measure of LDH concentration. - ∞), (e), (8)

. (a) 1.7×10^{-7} M (b) 0.33; 0.67; 0.91 (c) The upper curve corresponds to enzyme B ($[X] > K_m$ for this enzyme); the lower curve, enzyme A. . (a) 400 s^{-1} ! (b) 10 pM (c) $a = 2$, $a' = 3$ (d)

Mixed inhibitor 10. (a) 24 nM (b) 4 μM (V_o is exactly half V_{max} , so $[A] = K_m$) (c) 40 μM (V_o is exactly half V_{max} , So $[A] = 10$ times K_m in the presence of inhibitor) (d) No. $K_{\text{eq}}/K_m = (0.33 \text{ s}^{-1})/(4 \times 10^7 \text{ s}^{-1}) = 8.25 \times 10^{-9}$! s^{-1} , well below the diffusion-controlled limit. $V_{\text{max}} \sim 140 \text{ p/min}$; $K_m \sim 1 \times 10^7 \text{ M}$ (a) $V_{\text{max}} = 51.5 \text{ mm/min}$; $K_m = 0.59 \text{ mm}$ (b) Competitive inhibition $K_y = 2.2 \text{ mM}$; $V_{\text{max}} = 0.50 \text{ mmol/min}$ Curve A $K_{\text{eq}} = 2.0 \times 10^7 \text{ min}^{-1}$ The basic assumptions of the Michaelis-Menten equation still hold. The reaction is at steady state, and the rate is determined by $V_o = k_2 [ES]$. The equations needed to solve for $[ES]$ are $(E)(1 - [E]) = \frac{[E]}{[EI] K}$, $[E]$ can be obtained by rearranging Eqn 6-19. The rest follows the pattern of the Michaelis-Menten equation derivation in the text. Minimum $M_i = 29,000$ $[E] = [E] + [ES] + [EI]$ and

18. 19. 20. 21. 22. 23. Activity of the prostate enzyme equals total phosphatase activity in a blood sample minus phosphatase activity in the presence of enough tartrate to completely inhibit the prostate enzyme. The inhibition is mixed. Because K_m seems not to change appreciably, this could be the special case of mixed inhibition called noncompetitive. The $[S]$ at which $V_o = V_{ya}/2$ is obtained when all terms except V_{max} on the right side of Eqn 6-30—that is, $[S]/((K_y + a'[S])$ —equal 4'. Begin with $[S](a_k + a'[S]) = Y_{a'}$ and solve for $[S]$. The optimum activity occurs when Glu^u is protonated and Asp^u is unprotonated. (a) Increase factor = 1.96; $V_o = 50 \text{ } \mu\text{m s}^{-1}$; increase factor = 1.048. (b) When $a = 2.0$, the curve is shifted to the right as the K_m is increased by a factor of 2. When $a' = 3.0$, the asymptote of the curve (the V_{max}) declines by a factor of 3. When $a = 2.0$ and $a' = 3.0$, the curve briefly rises above the curve where both a and $a' = 1.0$, due to a decline in K_m . However, the asymptote is lower, because V_{max} declines by a factor of 3. (c) When $a = 2.0$, the x intercept moves to the right. When $a = 2.0$ and $a' = 3.0$, the x intercept moves to the left. (a) In the wild-type enzyme, the substrate is held in place by a hydrogen bond and an ion-dipole interaction between the charged side chain of Arg^l and the polar carbonyl of pyruvate. During catalysis, the charged Arg^l side chain also stabilizes the polarized carbonyl transition state. In the mutant, the binding is reduced to just a hydrogen bond, substrate binding is weaker, and ionic stabilization of the transition state is lost, reducing catalytic activity. (b) Because Lys and Arg are roughly the same size and have a similar positive charge, they probably have very similar properties. Furthermore, because pyruvate binds to Arg^l by (presumably) an ionic interaction, an Arg to Lys mutation would probably have little effect on substrate binding. (c) The “forked” arrangement aligns two positively charged groups of Arg residues with the negatively charged oxygens of pyruvate and facilitates two combined hydrogen-bond and ion-dipole interactions. When Lys is present, only one such combined hydrogen-bond and ion-dipole interaction is possible, thus reducing the strength of the interaction. The positioning of the substrate is less precise. (d) Ile interacts hydrophobically with the ring of NADH. This type of interaction is not possible with the hydrophilic side chain of Gln. (e) The structure is shown below. (f) The mutant enzyme rejects

pyruvate because pyruvate's hydrophobic methyl group will not interact with the highly hydrophilic guanidinium group of Arg!TM. The mutant binds oxaloacetate because of the strong ionic interaction between the Arg!" side chain and the carboxyl of oxaloacetate. (g) The protein must be flexible enough to accommodate the added bulk of the side chain and the larger substrate.

AS-7 Abbreviated Solutions to Problems Chapter 7 1. 10. 11. 12. 13. 14. 15. With reduction of the carbonyl oxygen to a hydroxyl group, the chemistry at C-1 and C-3 is the same; the glycerol molecule is not chiral. . Epimers differ by the configuration about only one carbon. (a) b-altrose (C-2), D-glucose (C-3), D-gulose (C-4) (b) b-idose (C-2), D-galactose (C-3), D-allose (C-4) (c) b-arabinose (C-2), D-xylose (C-3) . Osazone formation destroys the configuration around C-2 of aldoses, so aldoses differing only at the C-2 configuration give the same derivative, with the same melting point. . To convert a-D-glucose to B-D-glucose, the bond between C-1 and the hydroxyl on C-5 (as in Fig. 7-6). To convert D-glucose to D-mannose, either the —H or the —OH on C-2. Conversion between chair conformations does not require bond breakage; this is the critical distinction between configuration and conformation. . No; glucose and galactose differ at C-4. . (a) Both are polymers of D-glucose, but they differ in the glycosidic linkage: (@1—4) for cellulose, (a1—4) for glycogen. (b) Both are hexoses, but glucose is an aldohexose, fructose a ketohexose. (c) Both are disaccharides, but maltose has two (a11—4)-linked D-glucose units; sucrose has (a1 < > 26)-linked D-glucose and D-fructose.

CH₂OH 0. H H H OH
HO g OH reducing sugar . A hemiacetal is formed when an aldose or ketose condenses with an alcohol; a glycoside is formed when a hemiacetal condenses with an alcohol (see Fig. 7-5). . Fructose cyclizes to either the pyranose or the furanose structure. Increasing the temperature shifts the equilibrium in the direction of the furanose, the less sweet form. The rate of mutarotation is sufficiently high that, as the enzyme consumes B-D-glucose, more a-D-glucose is converted to the B form and, eventually, all the glucose is oxidized. Glucose oxidase is specific for glucose and does not detect other reducing sugars (such as galactose) that react with Fehling's reagent. (a) Measure the change in optical rotation with time. (b) The optical rotation of the mixture is negative (inverted) relative to that of the sucrose solution. (e) —2.0° Prepare a slurry of sucrose and water for the core; add a small amount of sucrase

(invertase); immediately coat with chocolate. Sucrose has no free anomeric carbon to undergo mutarotation. $\text{CHOH} > \text{r} > \text{H H O}$
 $\text{CH, O, OH H HO H H H OH OH H H OH HO H H OH}$ Yes; yes N-Acetyl-6-D-glucosamine is a reducing sugar; its C-1 can be oxidized (see p. 252). p-Gluconate is not a reducing sugar; its C-1 is already at the oxidation state of a carboxylic acid. GlcN(al < la)Glc is not a reducing sugar; the anomeric carbons of both monosaccharides are involved in the glycosidic bond.

AS-8 Abbreviated Solutions to Problems 16. 17. 18. 19. 20. 21. 22. 23. 24. 25. 26. 27. 28. 29. Humans lack cellulase in the gut and cannot break down cellulose. Native cellulose consists of glucose units linked by $(1 \rightarrow 4)$ glycosidic bonds, which force the polymer chain into an extended conformation. Parallel series of these extended chains form intermolecular hydrogen bonds, aggregating into long, tough, insoluble fibers. Glycogen consists of glucose units linked by $(\alpha-1 \rightarrow 4)$ glycosidic bonds, which cause bends in the chain and prevent formation of long fibers. In addition, glycogen is highly branched and, because many of its hydroxyl groups are exposed to water, is highly hydrated and disperses in water. Cellulose is a structural material in plants, consistent with its side-by-side aggregation into insoluble fibers. Glycogen is a storage fuel in animals. Highly hydrated glycogen granules with their many nonreducing ends are rapidly hydrolyzed by glycogen phosphorylase to release glucose 1-phosphate. Cellulose is several times longer; it assumes an extended conformation, whereas amylose has a helical structure. 6,000 residues/s

11s The ball-and-stick model of the disaccharide in Fig. 7-18b shows no steric interactions, but a space-filling model, showing atoms with their real relative sizes, would show several strong steric hindrances in the ${}^{170^\circ}$, ${}^{170^\circ}$ conformer that are not present in the 30° , ${}^{40^\circ}$ conformer. The negative charges on chondroitin sulfate repel each other and force the molecule into an extended conformation. The polar molecule attracts many water molecules, increasing the molecular volume. In the dehydrated solid, each negative charge is counterbalanced by a positive ion, and the molecule condenses. Positively charged amino acid residues would bind the highly negatively charged groups on heparin. In fact, Lys residues of antithrombin II interact with heparin. 8 possible sequences, 144 possible linkages, and 64 stereochemical possibilities, for a total of 73,728 permutations! Oligosaccharide chains: 0 Electrophoresis 1 2

1 = : © Oligosaccharides; their subunits can be combined in more ways than the amino acid subunits of oligopeptides. Each hydroxyl group can participate in glycosidic bonds, and the configuration of each glycosidic bond can be either a or B. The polymer can be linear or branched. (a) Branch-point residues yield 2,3-di-O-methylglucose; the unbranched residues yield 2,3,6-tri-O-methylglucose. (b) 3.75% Chains of $(1 \rightarrow 6)$ -linked D-glucose

residues with occasional (1—3)-linked branches, with about one branch every 20 residues (a) The tests involve trying to dissolve only part of the sample in a variety of solvents, then analyzing both dissolved and undissolved materials to see whether their compositions differ. (b) For a pure substance, all molecules are the same and any dissolved fraction will have the same composition as any undissolved fraction. An impure substance is a mixture of more than one compound. When treated with a particular solvent, more of one component may dissolve, leaving more of the other component(s) behind. As a result, the dissolved and undissolved fractions have different compositions. (c) A quantitative assay allows researchers to be sure that none of the activity has been lost through degradation. When determining the structure of a molecule, it is important that the sample under analysis consist only of intact (undegraded) molecules. If the sample is contaminated with degraded material, this will give confusing and perhaps uninterpretable structural results. A qualitative assay would detect the presence of activity, even if it had become significantly degraded. (d) Results 1 and 2. Result 1 is consistent with the known structure, because type B antigen has three molecules of galactose; types A and O each have only two. Result 2 is also consistent, because type A has two amino sugars (N-acetylgalactosamine and N-acetylglucosamine); types B and O have only one (N-acetylglucosamine). Result 3 is not consistent with the known structure: for type A, the glucosamine: galactosamine ratio is 1:1; for type B, it is 1:0. (e) The samples were probably impure and/or partly degraded. The first two results were correct possibly because the method was only roughly quantitative and thus not as sensitive to inaccuracies in measurement. The third result is more quantitative and thus more likely to differ from predicted values because of impure or degraded samples. (f) An exoglycosidase. If it were an endoglycosidase, one of the products of its action on O antigen would include galactose, N-acetylglucosamine, or N-acetylgalactosamine, and at least one of those sugars would be able to inhibit the degradation. Given that the enzyme is not inhibited by any of these sugars, it must be an exoglycosidase, removing only the terminal sugar from the chain. The terminal sugar of O antigen is fucose, so fucose is the only sugar that could inhibit the degradation of O antigen. (g) The exoglycosidase removes N-acetylgalactosamine from A antigen and galactose from B antigen.

Because fucose is not a product of either reaction, it will not prevent removal of these sugars, and the resulting substances will no longer be active as A or B antigen. However, the products should be active as O antigen, because degradation stops at fucose. Ch) All the results are consistent with Fig. 10-15. (1) p-Fucose and L-galactose, which would protect against degradation, are not present in any of the antigens. (2) The terminal sugar of A antigen is N-acetylgalactosamine, and this sugar alone protects this antigen from degradation. (3) The terminal sugar of B antigen is galactose, which is the only sugar capable of protecting this antigen. Chapter 8 1. 2. N-3 and N-7 (5')GCGCAATATTTTGAGAAATATTGCGC(3'); it contains a palindrome. The individual strands can form hairpin structures; the two strands can form a cruciform. .94X10%7¢ 4. (a) 40° (b) 0° 5. The RNA helix is in the A conformation; the DNA helix is generally in the B conformation. 6. In eukaryotic DNA, about 5% of C residues are methylated. 5-Methylcytosine can spontaneously deaminate to form thymine; the resulting G—T pair is one of the most common mismatches in eukaryotic cells. 7. Higher 8. Without the base, the ribose ring can be opened to generate the noncyclic aldehyde form. This, and the loss of base-stacking interactions, could contribute significant flexibility to the DNA backbone. 9. C@CGCGTGCGGCGCG 10. Base stacking in nucleic acids tends to reduce the absorption of UV light. Denaturation involves loss of base stacking, and UV absorption increases. 11. 0.35 mg/mL 12. HOCH, O. oH I i HN “O= i H H | H a | | X -o-o a aa | HO H H2N H OH Deoxyribose Guanine Phosphate

13. 14. 15. 16. 17. 18. 19. Solubilities: phosphate > deoxyribose > guanine. The highly polar phosphate groups and sugar moieties are on the outside of the double helix, exposed to water; the hydrophobic bases are in the interior of the helix. If dCTP is omitted, when the first G residue is encountered in the template, ddCTP will be added, and polymerization will halt. Only one band will be seen in the sequencing gel. WLI Electrophoresis II (5')P—GCGCCAUUGC(3')—OH 5')P—GCGCCAUUGC(3')—OH 5')P—GCGCCAUU(3')—OH 5')P—GCGCCA(3')—OH 5')P—GCGCCA(3')—OH 5')P—GCGCC(3')—OH 5')P—GCGC(3')—OH 5')P—GCG(3')—OH 5')P—GC(8')—OH and the nucleoside 5'-phosphates (a) Water is a participant in most biological reactions, including those that cause mutations. The low water content in endospores reduces the activity of mutation-causing enzymes and slows the rate of nonenzymatic depurination reactions, which are hydrolysis reactions. (b) UV light induces formation of cyclobutane pyrimidine dimers. Because *B. subtilis* is a soil organism, spores can be lofted to the top of the soil or into the air, where they may be subject to prolonged UV exposure. DMT is a blocking group that prevents reaction of the incoming base with itself. (a) Right-handed. The base at one 5' end is adenine; at the other 5' end, cytidine. (b) Left-handed (c) If you cannot see the structures in stereo, see additional tips in the expanded solutions manual, or use a search engine to find tips online. (a) It would not be easy! The data for different samples from the same organism show significant variation, and the recovery is never 100%. The numbers for C and T show much more consistency than those for A and G, so for C and T it is much easier to make the case that samples from the same organism have the same composition. But even with the less consistent values for A and G, (1) the range of values for different tissues does overlap substantially; (2) the difference between different preparations of the same tissue is about the same as the difference between samples from different tissues; and (3) in samples for which recovery is high, the numbers are more consistent. (b) This technique would not be sensitive enough to detect a difference between normal and cancerous cells. Cancer is caused by mutations, but these changes in DNA—a few base pairs out of several billion—would be too small to detect with these techniques. (c) The ratios of A:G and T:C vary widely among different species. For example, in the bacterium

Serratia marcescens, both ratios are 0.4, meaning that the DNA contains mostly G and C. In *Haemophilus influenzae*, by contrast, the ratios are 1.74 and 1.54, meaning that the DNA is mostly A and T. (d) Conclusion 4 has three requirements. A = T: The table shows an A:T ratio very close to 1 in all cases. Certainly, the variation in this ratio is substantially less than the variation in Abbreviated Solutions to Problems AS-9 the A:G and T:C ratios. G = C: Again, the G:C ratio is very close to 1, and the other ratios vary widely. (A + G) = (T + C): This is the purine:pyrimidine ratio, which also is very close to 1. (e) The different "core" fractions represent different regions of the wheat germ DNA. If the DNA were a monotonous repeating sequence, the base composition of all regions would be the same. Because different core regions have different sequences, the DNA sequence must be more complex. Chapter 9 1. At this point, one could treat the DNA as in (b) or (d), then ligate a synthetic DNA fragment with the BamHI recognition sequence between the two resulting blunt ends. Method 2 (more efficient): Synthesize a DNA fragment with the structure (5')AATTGGATCC(3') (3')\CCTAGGTAA(5') This would ligate efficiently to the sticky ends generated by EcoRI cleavage, would introduce a BamHI site, but would not regenerate the EcoRI site. (i) The four fragments (with N = any nucleotide), in order of discussion in the problem, are (5')AATTCNNNNCTGCA(3') (3')GNNNNG(5') (5')AATTCNNNNGTGCA(3') (3')GNNNNC(5') (5')AATTGNNNNCTGCA(3') (3')CNNNNG(5') (5')AATTGNNNNGTGCA(3') (3')CNNNNC(5') . A phage DNA can be packaged into infectious phage particles only if it is between 40,000 and 53,000 bp in length. Since bacteriophage vectors generally include about 30,000 bp (in two pieces), they will not be packaged into phage particles unless they contain a sufficient length of inserted DNA (10,000 to 23,000 bp). . (a) Plasmids in which the original pBR322 was regenerated without insertion of a foreign DNA fragment; these would retain resistance to ampicillin. Also,

two or more molecules of pBR322 might be ligated together with or without insertion of foreign DNA. (b) The clones in lanes 1 and 2 each have one DNA fragment inserted in different orientations. The clone in lane 3 has two DNA fragments, ligated such that the EcoRI proximal ends are joined. (5')GAAAGTCCGCGTTATAGGCATG(3') (3')ACGTCTTTCAGGCGCAATATCCGTACTTAA(5') . Your test would require DNA primers, a heat-stable DNA polymerase, deoxynucleoside triphosphates, and a PCR machine (thermal cycler). The primers would be designed to amplify a DNA segment encompassing the CAG repeat. The DNA strand shown is the coding strand, oriented 5'—> 3' left to right. The primer targeted to DNA to the left of the repeat would be identical to any 25-nucleotide sequence shown in the region to the left of the CAG repeat. The primer on the right

AS-10 Abbreviated Solutions to Problems 10. 11. 12. side must be complementary and antiparallel to a 25-nucleotide sequence to the right of the CAG repeat. Using the primers, DNA including the CAG repeat would be amplified by PCR, and its size would be determined by comparison to size markers after electrophoresis. The length of the DNA would reflect the length of the CAG repeat, providing a simple test for the disease. . Design PCR primers that are complementary to the DNA in the deleted segment but that would direct DNA synthesis away from each other. No PCR product will be generated unless the ends of the deleted segment are joined to create a circle. . The plant expressing firefly luciferase must take up luciferin, the substrate of luciferase, before it can “glow” (albeit weakly). The plant expressing green fluorescent protein glows without requiring any other compound. . Primer 1: CCTCGAGTCAATCGATGCTG Primer 2: CGCGCACATCAGACGAACCA Recall that all DNA sequences are always written in the 5’ to 3’ direction, left to right; that the two strands of a DNA molecule are antiparallel; and that both PCR primers must target the end sequences so that their 3’ ends are oriented toward the segment to be amplified. In a lab, writing a sequence in the wrong orientation on an order form when ordering a synthetic oligonucleotide primer can be a very expensive mistake. . 9 1 5 3 7 4 2 6 8 f F | The production of labeled antibodies is difficult and expensive. The labeling of every antibody to every protein target would be impractical. By labeling one antibody preparation for binding to all antibodies of a particular class, the same labeled antibody preparation can be used in many different immunofluorescence experiments. Express the protein in yeast strain 1 as a fusion protein with one of the domains of Gal4p—say, the DNA-binding domain. Using yeast strain 2, make a library in which essentially every protein of the fungus is expressed as a fusion protein with the interaction domain of Gal4p. Mate strain 1 with the strain 2 library, and look for colonies that are colored due to expression of the reporter gene. These colonies will generally arise from mated cells containing a fusion protein that interacts with your target protein. Cover spot 4, add solution containing activated T, irradiate, wash. 1. A-T 2.  1 and 2, add solution containing activated G, irradiate, wash. 1. A-
 T-G-C 2. G-T-C-C 83. A-T-G-C 4. G-C-C-C . The primers can be used
 to probe libraries containing long genomic clones to identify contig
 ends that lie close to each other. If the contigs flanking the gap are
 close enough, the primers can be used in PCR to directly amplify
 the intervening DNA separating the contigs, which can then be
 cloned and sequenced. .

ATSAAGWDEWEGGKVLHLDGKLQNRGALLELDIGAV . The same
 disease condition can be caused by defects in two or more genes,
 which are on different chromosomes. . (a) DNA solutions are highly
 viscous because the very long molecules are tangled in solution.
 Shorter molecules tend to tangle less and form a less viscous
 solution, so decreased viscosity corresponds to shortening of the
 polymers—as caused by nuclease activity. (b) An endonuclease. An
 exonuclease removes single nucleotides from the 5' or 3' end and
 would produce TCA-soluble ³²P-labeled nucleotides. An
 endonuclease cuts DNA into oligonucleotide fragments and
 produces little or no TCA-soluble ³²P-labeled material. (c) The 5'
 end. If the phosphate were left on the 3' end, the kinase would
 incorporate significant ³²P as it added phosphate to the 5' end;
 treatment with the phosphatase would have no effect on this. In this
 case, samples A and B would incorporate significant amounts of
³²P. When the phosphate is left on the 5' end, the kinase does not
 incorporate any ³²P: it cannot add a phosphate if one is already
 present. Treatment with the phosphatase removes 5' phosphate, and
 the kinase then incorporates significant amounts of ³²P. Sample A
 will have little or no ³²P, and B will show substantial ³²P
 incorporation—as was observed. (d) Random breaks would produce
 a distribution of fragments of random size. The production of
 specific fragments indicates that the enzyme is site-specific. (e)
 Cleavage at the site of recognition. This produces a specific
 sequence at the 5' end of the fragments. If cleavage occurred near
 but not within the recognition site, the sequence at the 5' end of the
 fragments would be random. (f) The results are consistent with two
 recognition sequences, as shown below, cleaved where shown by
 the arrows, (5')--- GTT AAC --- (3') (3')- — CAA TTG — —(5')
 which gives the (5')pApApC and (3')TpTp fragments, and (5')---

GTC GAC --- (3') (3')--- CAG CTG---(5') A which gives the (5')pGpApC and (3')CpTp fragments Chapter 10 1. The term “lipid” does not specify a particular chemical structure. Compounds are categorized as lipids based on their greater solubility in organic solvents than in water. . (a) The number of cis double bonds. Each cis double bond causes a bend in the hydrocarbon chain, lowering the melting temperature. (b) Six different triacylglycerols can be constructed, in order of increasing melting points: 000 < OOP = OPO < PPO = POP < PPP where O = oleic and P = palmitic acid. The greater the content of saturated fatty acid, the higher is the melting point. (Cc) Branched-chain fatty acids increase the fluidity of membranes because they decrease the extent of membrane lipid packing. . Lecithin, an amphipathic compound, is an emulsifying agent, facilitating the solubilization of butter.

Squalene 5. Spearmint is (R)-carvone; caraway is (S)-carvone. 6. $\text{COOH COOH H}-\text{C}-\text{NH}$, $\text{H}_2\text{N}-\text{C}-\text{H CH}_2\text{CH}_2$, (R)-2-Aminopropanoic acid (S)-2-Aminopropanoic acid $\text{OH COOH H}_2\text{C}-\text{C}-\text{COOH H}_2\text{C}-\text{C}-\text{OH H H}$ (R)-2-Hydroxypropanoic acid (S)-2-Hydroxypropanoic acid 7. Hydrophobic units: (a) 2 fatty acids; (b), (c), and (d) 1 fatty acid and the hydrocarbon chain of sphingosine; (e) steroid nucleus and acyl side chain. Hydrophilic units: (a) phosphoethanolamine; (b) phosphocholine; (c) D-galactose; (d) several sugar molecules; (e) alcohol group (OH) 8. O Y Re SAA AAAA AANA 70 9. It reduces double bonds, which increases the melting point of lipids containing the fatty acids. 10. The triacylglycerols of animal fats (grease) are hydrolyzed by NaOH (saponified) to form soaps, which are much more soluble in water than are triacylglycerols. 11. It could only be a sphingolipid (sphingomyelin). 12. A S ji T 0. *Ls0a i a as ad H © *NH; (O) Phosphatidylserine 13. Long, saturated acyl chains, nearly solid at air temperature, form a hydrophobic layer in which a polar compound such as HO cannot dissolve or diffuse. 14. (a) The free —OH group on C-2 and the phosphocholine head group on C-3 are hydrophilic; the fatty acid on C-1 of lysolecithin is hydrophobic. (b) Certain steroids such as prednisone inhibit the action of phospholipase A₂, inhibiting the release of arachidonic acid from C-2. Arachidonic acid is converted to a variety of eicosanoids, some of which cause inflammation and pain. (c) Phospholipase A₂ releases arachidonic acid, a precursor of other eicosanoids with vital protective functions in the body; it also breaks down dietary glycerophospholipids. 15. The part of the membrane lipid that determines blood type is the oligosaccharide in the head group of the membrane sphingolipids (see Fig. 10-15). This same oligosaccharide is attached to certain membrane glycoproteins, which also serve as points of recognition by the antibodies that distinguish blood groups. Abbreviated Solutions to Problems AS-11 16. Diacylglycerol is hydrophobic and remains in the membrane. Inositol 1,4,5-trisphosphate is highly polar, very soluble in water, and more readily diffusible in the cytosol. Both are second messengers. 17. Water-soluble vitamins are more rapidly excreted in the urine and are not stored effectively. Fat-soluble vitamins have very low solubility in water and are stored in body lipids. 18. (a) Glycerol and the sodium salts of palmitic and stearic acids. (Cb) b-

Glycerol 3-phosphocholine and the sodium salts of palmitic and oleic acids. 19. Solubilities in water: monoacylglycerol > diacylglycerol > triacylglycerol. 20. First eluted to last eluted: cholesteryl palmitate and triacylglycerol; cholesterol and n-tetradecanol; phosphatidylcholine and phosphatidylethanolamine; sphingomyelin; phosphatidylserine and palmitate. 21. (a) Subject acid hydrolysates of each compound to chromatography (GLC or silica gel TLC) and compare the result with known standards. Sphingomyelin hydrolysate: sphingosine, fatty acids, phosphocholine, choline, and phosphate; cerebroside hydrolysate: sphingosine, fatty acids, sugars, but no phosphate. (b) Strong alkaline hydrolysis of sphingomyelin yields sphingosine; phosphatidylcholine yields glycerol. Detect hydrolysate components on thin-layer chromatograms by comparing with standards or by their differential reaction with FDNB (only sphingosine reacts to form a colored product). Treatment with phospholipase A₂ or A₁ releases free fatty acids from phosphatidylcholine, but not from sphingomyelin. 22. Phosphatidylethanolamine and phosphatidylserine. 23. (a) GM1 and globoside. Both glucose and galactose are hexoses, so “hexose” in the molar ratio refers to glucose + galactose. The ratios for the four gangliosides are: GM1, 1:3:1:1; GM2, 1:2:1:1; GMB, 1:2:0:1; globoside, 1:3:1:0. (b) Yes. The ratio matches GM2, the ganglioside expected to build up in Tay-Sachs disease (see Box 10-1, Fig. 1). (c) This analysis is similar to that used by Sanger to determine the amino acid sequence of insulin. The analysis of each fragment reveals only its composition, not its sequence, but because each fragment is formed by sequential removal of one sugar, we can draw conclusions about sequence. The structure of the normal asialoganglioside is ceramide-glucose-galactose—galactosamine-galactose, consistent with Box 10-1 (excluding Neu5Ac, removed before hydrolysis). (d) The Tay-Sachs asialoganglioside is ceramide—glucose-galactose—galactosamine, consistent with Box 10-1. (e) The structure of the normal asialoganglioside, GM1, is: ceramide-glucose (2 —OH involved in glycosidic links; 1 —OH involved in ring structure; 3 —OH (2,3,6) free for methylation)—galactose (2 —OH in links; 1 —OH in ring; 3 —OH (2,4,6) free for methylation)—galactosamine (2 —OH in links; 1 —OH in ring; 1 —NH₂; instead of an —OH; 2 —OH (4,6) free for methylation)—galactose (1 —OH in link; 1 —OH in ring; 4 —OH (2,3,4,6) free for methylation). (f) Two key pieces of

information are missing: What are the linkages between the sugars? Where is Neu5Ac attached? Chapter 11

1. The area per molecule would be calculated from the known amount (number of molecules) of lipid used and the area occupied by a monolayer when it begins to resist compression (when the required force increases dramatically, as shown in the plot of force vs. area).
2. The data support a bilayer of lipid in the dog erythrocytes: a single cell, with surface area $98 \mu\text{m}^2$, has a lipid monolayer area of $200 \mu\text{m}^2$. In the case of sheep and human erythrocytes, the data suggest a monolayer, not a bilayer. In fact, significant

AS-12 Abbreviated Solutions to Problems 10. 11. 12. 13. 14. 15. 16. 17. 18. 19. 20. 21. experimental errors occurred in these early experiments; recent, more accurate measurements support a bilayer in all cases. . 63 SDS molecules per micelle . (a) Lipids that form bilayers are amphipathic molecules: they contain a hydrophilic and a hydrophobic region. To minimize the hydrophobic area exposed to the water surface, these lipids form two-dimensional sheets, with the hydrophilic regions exposed to water and the hydrophobic regions buried in the interior of the sheet. Furthermore, to avoid exposing the hydrophobic edges of the sheet to water, lipid bilayers close on themselves. (b) These sheets form the closed membrane surfaces that envelop cells and compartments within cells (organelles). . 2 nm. Two palmitates placed end to end span about 4 nm, approximately the thickness of a typical bilayer. . Decrease. Movement of individual lipids in bilayers occurs much faster at 37°C, when the lipids are in the “fluid” phase, than at 10°C, when they are in the “solid” phase. . 35 kJ/mol, neglecting the effects of transmembrane electrical potential; 0.60 mol. . 13 kJ/mol. . Most of the O_2 consumed by a tissue is for oxidative phosphorylation, the source of most of the ATP. Therefore, about two-thirds of the ATP synthesized by the kidney is used for pumping K^+ and Na^+ . No. The symporter may carry more than one equivalent of Na^+ for each mole of glucose transported. Salt extraction indicates a peripheral location, and inaccessibility to protease in intact cells indicates an internal location. X seems to be a peripheral protein on the cytosolic face of the membrane. The hydrophobic interactions among membrane lipids are noncovalent and reversible, allowing membranes to spontaneously reseal. The temperature of body tissues at the extremities is lower than that of tissues closer to the center of the body. If lipid is to remain fluid at this lower temperature, it must contain a higher proportion of unsaturated fatty acids; unsaturated fatty acids lower the melting point of lipid mixtures. The energetic cost of moving the highly polar, sometimes charged, head group through the hydrophobic interior of the bilayer is prohibitive. At pH 7, tryptophan bears a positive and a negative charge, but indole is uncharged. The movement of the less polar indole through the hydrophobic core of the bilayer is energetically more favorable. 3 x 10⁵ Treat a suspension of cells with unlabeled NEM in the

presence of excess lactose, remove the lactose, then add radiolabeled NEM. Use SDS-PAGE to determine the M_r of the radiolabeled band (the transporter). Construct a hydropathy plot; hydrophobic regions of 20 or more residues suggest transmembrane segments. Determine whether the protein in intact erythrocytes reacts with a membrane-impermeant reagent specific for primary amines; if so, the transporter is of type I. The leucine transporter is specific for the L isomer, but the binding site can accommodate either L-leucine or L-valine. Reduction of V_{max} in the absence of Na^+ indicates that leucine (or valine) is transported by symport with Na^+ . V_{max} reduced; K_m unaffected. $\sim 1\%$; estimated by calculating the surface area of the cell and of 10,000 transporter molecules (using the dimensions of hemoglobin (5.5 nm diameter, p. 163) as a model globular protein). The amino acids with the greatest hydropathy index (V, L, F, and C) are clustered on one side of the helix. This amphipathic helix is likely to dip into the lipid bilayer along its hydrophobic surface while exposing the other surface to the aqueous phase. Alternatively, a group of helices may cluster with their polar surfaces in contact with one another and their hydrophobic surfaces facing the lipid bilayer.

23. ~ 22 . To estimate the fraction of membrane surface covered by phospholipids, you would need to know (or estimate) the average cross-sectional area of a phospholipid molecule in a bilayer (e.g., from an experiment such as that diagrammed in problem 1 in this chapter) and the average cross-sectional area of a 50 kDa protein.

24. (a) The rise-per-residue for an α helix (Chapter 4) is about 1.5 Å = 0.15 nm. To span a 4 nm bilayer, an α helix must contain about 27 residues; thus for seven spans, about 190 residues are required. A protein of M_r 64,000 has about 580 residues. (b) A hydropathy plot is used to locate transmembrane regions. (c) Because about half of this portion of the epinephrine receptor consists of charged residues, it probably represents an intracellular loop that connects two adjacent membrane-spanning regions of the protein. (d) Because this helix is composed mostly of hydrophobic residues, this portion of the receptor is probably one of the membrane-spanning regions of the protein.

25. (a) Model A: supported. The two dark lines are either the protein layers or the phospholipid heads, and the clear space is either the bilayer or the hydrophobic core, respectively. Model B: not supported. This model requires a more-or-less uniformly stained band surrounding the cell.

Model C: supported, with one reservation. The two dark lines are the phospholipid heads; the clear zone is the tails. This assumes that the membrane proteins are not visible, because they do not stain with osmium or do not happen to be in the sections viewed. (b) Model A: supported. A “naked” bilayer (4.5 nm) + two layers of protein (2 nm) sums to 6.5 nm, which is within the observed range of thickness. Model B: neither. This model makes no predictions about membrane thickness. Model C: unclear. The result is hard to reconcile with this model, which predicts a membrane as thick as, or slightly thicker than (due to the projecting ends of embedded proteins), a “naked” bilayer. The model is supported only if the smallest values for membrane thickness are correct or if a substantial amount of protein projects from the bilayer. (c) Model A: unclear. The result is hard to reconcile with this model. If the proteins are bound to the membrane by ionic interactions, the model predicts that the proteins contain a high proportion of charged amino acids, in contrast to what was observed. Also, because the protein layer must be very thin (see (b)), there would not be much room for a hydrophobic protein core, so hydrophobic residues would be exposed to the solvent. Model B: supported. The proteins have a mixture of hydrophobic residues (interacting with lipids) and charged residues (interacting with

water). Model C: supported. The proteins have a mixture of hydrophobic residues (anchoring in the membrane) and charged residues (interacting with water). (d) Model A: unclear. The result is hard to reconcile with this model, which predicts a ratio of exactly 2.0; this would be hard to achieve under physiologically relevant pressures. Model B: neither. This model makes no predictions about amount of lipid in the membrane. Model C: supported. Some membrane surface area is taken up with proteins, so the ratio would be less than 2.0, as was observed under more physiologically relevant conditions. (e) Model A: unclear. The model predicts proteins in extended conformations rather than globular, so supported only if one assumes that proteins layered on the surfaces include helical segments. Model B: supported. The model predicts mostly globular proteins (containing some helical segments). Model C: supported. The model predicts mostly globular proteins. (f) Model A: unclear. The phosphorylamine head groups are protected by the protein layer, but only if the proteins completely cover the surface will the phospholipids be completely protected from phospholipase. Model B: supported. Most head groups are accessible to phospholipase. Model C: supported. All head groups are accessible to phospholipase. (g) Model A: not supported. Proteins are entirely accessible to trypsin digestion and virtually all will undergo multiple cleavage, with no protected hydrophobic segments. Model B: not supported. Virtually all proteins are in the bilayer and inaccessible to trypsin. Model C: supported. Segments of protein that penetrate or span the bilayer are protected from trypsin; those exposed at the surfaces will be cleaved. The trypsin-resistant portions have a high proportion of hydrophobic residues.

Chapter 12 1. X is cAMP; its production is stimulated by epinephrine. (a) Centrifugation sediments adenylyl cyclase (which catalyzes cAMP formation) in the particulate fraction. (b) Added cAMP stimulates glycogen phosphorylase. (c) cAMP is heat stable; it can be prepared by treating ATP with barium hydroxide. . Unlike cAMP, dibutyryl cAMP passes readily through the plasma membrane. . (a) It increases [cAMP]. (b) cAMP regulates Na⁺ permeability. (c) Replace lost body fluids and electrolytes. . (a) The mutation makes R unable to bind and inhibit C, so C is constantly active. (b) The mutation prevents cAMP binding to R, leaving C inhibited by bound R. . Albuterol raises [cAMP], leading to

relaxation and dilation of the bronchi and bronchioles. Because B-adrenergic receptors control many other processes, this drug would have undesirable side effects. To minimize them, find an agonist specific for the subtype of B-adrenergic receptors found in the bronchial smooth muscle. . Hormone degradation; hydrolysis of GTP bound to a G protein; degradation, metabolism, or sequestration of second messenger; receptor desensitization; removal of receptor from the cell surface. . Fuse CFP to B-arrestin and YFP to the cytoplasmic domain of the B-adrenergic receptor, or vice versa. In either case, illuminate at 433 nm and observe at both 476 and 527 nm. If the interaction occurs, emitted light intensity will decrease at 476 nm and increase at 527 nm on addition of epinephrine to cells expressing the fusion proteins. If the interaction does not occur, the wavelength of emitted light will remain at 476 nm. Some reasons why this might fail: The fusion proteins (1) are inactive or otherwise unable to interact, (2) are not translocated to their normal subcellular location, or (8) are not stable to proteolytic breakdown. . Vasopressin acts by elevating cytosolic $[Ca^{2+}]$ to 10^{-7} M, activating protein kinase C. EGTA injection blocks vasopressin action but should not affect the response to glucagon, which uses cAMP, not Ca^{2+} , as second messenger. 10. 11. 12. 13. 14. 15. 16. 17. 18. 19. 20. Abbreviated Solutions to Problems AS-13 .

Amplification results as one molecule of a catalyst activates many molecules of another catalyst, in an amplification cascade involving, in order, insulin receptor, IRS-1, Raf, MEK, ERK; ERK activates a transcription factor, which stimulates mRNA production. A mutation in ras that inactivates the Ras GTPase activity creates a protein that, once activated by the binding of GTP, continues to give, through Raf, the insulin-response signal. Shared properties of Ras and G α ; Both bind either GDP or GTP; both are activated by GTP; both, when active, activate a downstream enzyme; both have intrinsic GTPase activity that shuts them off after a short period of activation. Differences between Ras and G α : Ras is a small, monomeric protein, G α is heterotrimeric. Functional difference between G α and G $\beta\gamma$: G α s activates adenylyl cyclase, G α i inhibits it. Kinase (factor in parentheses): PKA (cAMP); PKG (cGMP); PKC (Ca^{2+} , DAG); Ca^{2+} /CaM kinase (Ca^{2+} , CaM); cyclin-dependent kinase (cyclin); protein Tyr kinase (ligand for the receptor, such as insulin); MAPK (Raf); Raf (Ras); glycogen phosphorylase kinase (PKA). G $\beta\gamma$ remains in its activated form when the nonhydrolyzable

analog is bound. The analog therefore prolongs the effect of epinephrine on the injected cell. (a) Use the α -bungarotoxin—bound beads for affinity purification (see Fig. 3-17c) of AChR. Extract proteins from the electric organs and pass the mixture through the chromatography column, the AChR binds selectively to the beads. Elute the AChR with a solute that weakens its interaction with α -bungarotoxin. (b) Use binding of [^{125} I] α -bungarotoxin as a quantitative assay for AChR during purification by various techniques. At each step, assay AChR by measuring [^{125} I] α -bungarotoxin binding to the proteins in the sample. Optimize purification for the highest specific activity of AChR (counts/min of bound L [^{125} I] α -bungarotoxin per mg of protein) in the final material.

(a) No. If V_m were set by permeability to (primarily) K^+ , the Nernst equation would predict a V_m of -90 mV, not the observed -95 mV, so some other conductance must contribute to V_m . (b) Chloride ion is probably the determinant of V_m ; the predicted E_{Cl} is -94 mV. (a) V_m of the oocyte membrane changes from -60 mV to -10 mV—that is, the membrane is depolarized. (b) The effect of KCl depends on influx of Ca^{2+} from the extracellular medium. Hyperpolarization results in the closing of voltage-dependent Ca^{2+} channels in the presynaptic region of the rod cell. The resulting decrease in $[Ca^{2+}]_i$, diminishes release of an inhibitory neurotransmitter that suppresses activity in the next neuron of the visual circuit. When this inhibition is removed in response to a light stimulus, the circuit becomes active and visual centers in the brain are excited. (a) This would prevent influx of Na^+ and Ca^{2+} into the cells in response to light; the cone cells would fail to signal the brain that light had been received. Because rod cells are unaffected, the individuals would be able to see but would not have color vision. (b) This would prevent efflux of K^+ , which would lead to depolarization of the B-cell membrane and constitutive release of insulin into the blood. (c) ATP is responsible for closing this channel, so the channels will remain open, preventing depolarization of the B-cell membrane and release of insulin. Individuals with Oguchi disease might have a defect in rhodopsin kinase or in arrestin. Rod cells would no longer show any change in membrane potential in response to light. This experiment has been done. Illumination did activate PDE, but the enzyme could not significantly reduce the 8-Br-cGMP level, which remained well above that needed to keep the gated ion channels open. Thus, light

had no impact on membrane potential.

AS-14 Abbreviated Solutions to Problems 21. 22. 23. 24.

25. 26. (a) On exposure to heat, TRPV1 channels open, causing an influx of Na^+ and Ca^{2+} into the sensory neuron. This depolarizes the neuron, triggering an action potential. When the action potential reaches the axon terminus, neurotransmitter is released, signaling the nervous system that heat has been sensed. (b) Capsaicin mimics the effects of heat by opening TRPV1 at low temperature, leading to the false sensation of heat. The extremely low ECs, indicates that even very small amounts of capsaicin will have dramatic sensory effects. (c) At low levels, menthol should open the TRPM8 channel, leading to a sensation of cool; at high levels, both TRPM8 and TRPV3 will open, leading to a mixed sensation of cool and heat, such as you may have experienced with very strong peppermints.

(a) These mutations might lead to permanent activation of the PGE₂ receptor, leading to unregulated cell division and tumor formation.

(b) The viral gene might encode a constitutively active form of the receptor, causing a constant signal for cell division and thus tumor formation. (c) E1A protein might bind to pRb and prevent E2F from binding, so E2F is constantly active and cells divide uncontrollably.

(d) Lung cells do not normally respond to PGE₂, because they do not express the PGE₂ receptor; mutations resulting in a constitutively active PGE₂ receptor do not affect lung cells.

A normal tumor suppressor gene encodes a protein that restrains cell division. A mutant form of the protein fails to suppress cell division, but if either of the two alleles encodes normal protein, normal function will continue. A normal oncogene encodes a regulator protein that triggers cell division, but only when an appropriate signal (growth factor) is present. The mutant version of the oncogene product constantly sends the signal to divide, whether or not growth factors are present. In a child who develops multiple tumors in both eyes, every retinal cell had a defective copy of the Rb gene at birth. Early in the child's life, several cells independently underwent a second mutation that damaged the one good Rb allele, producing a tumor.

A child who develops a single tumor had, at birth, two good copies of the Rb gene in every cell; mutation in both Rb alleles in one cell (extremely rare) caused a single tumor. Two cells expressing the same surface receptor may have different complements of target proteins for protein phosphorylation.

(a) The cell-based model, which predicts different receptors present on different cells. (b) This

experiment addresses the issue of the independence of different taste sensations. Even though the receptors for sweet and/or umami are missing, the animals' other taste sensations are normal; thus, pleasant and unpleasant taste sensations are independent. (c) Yes. Loss of either T1R1 or T1R3 subunits abolishes umami taste sensation. (d) Both models. With either model, removing one receptor would abolish that taste sensation. (e) Yes. Loss of either the T1R2 or T1R3 subunits almost completely abolishes the sweet taste sensation; complete elimination of sweet taste requires deletion of both subunits. (f) At very high sucrose concentrations, T1R2 and, to a lesser extent, T1R3 receptors, as homodimers, can detect sweet taste. (g) The results are consistent with either model of taste encoding, but do strengthen the researchers' conclusions. Ligand binding can be completely separated from taste sensation. If the ligand for the receptor in "sweet-tasting cells" binds a molecule, mice prefer that molecule as a sweet compound. Chapter 13 1. Consider the developing chick as the system; the nutrients, egg shell, and outside world are the surroundings. Transformation of the single cell into a chick drastically reduces the entropy of the system. Initially, the parts of the egg outside the embryo are at © ND 11. 12. 13. 14. 15. 16. . LO 10. (the surroundings) contain complex fuel molecules (a low entropy condition). During incubation, some of these complex molecules are converted to large numbers of CO₂ and H₂O molecules (high entropy). This increase in the entropy of the surroundings is larger than the decrease in entropy of the chick (the system). . (a) —4.8 kJ/mol (b) 7.56 kJ/mol (c) —13.7 kJ/mol . (a) 262 (b) 608 (c) 0.30 . $\Delta G^\circ = -31$ kJ/mol . (a) —1.68 kJ/mol (b) —4.4 kJ/mol (c) At a given temperature, —7.6 kJ/mol the value of ΔG° for any reaction is fixed and is defined for standard conditions (here, both fructose 6-phosphate and glucose 6-phosphate at 1 M). In contrast, ΔG is a variable that can be calculated for any set of reactant and product concentrations. $K_a = 1$, $\Delta G^\circ \sim 0$. Less. The overall equation for ATP hydrolysis can be approximated as $\text{ATP}^* + \text{H}_2\text{O} \rightarrow \text{ADP}^* + \text{HPO}_4^{2-} + \text{H}^+$ (This is only an approximation, because the ionized species shown here are the major, but not the only, forms present.) Under standard conditions (i.e., $[\text{ATP}] = [\text{ADP}] = [\text{P}_i] = 1\text{M}$), the concentration of water is 55 M and does not change during the reaction. Because H^+ ions are produced in the reaction, at a higher $[\text{H}^+]$ (pH 5.0) the equilibrium would be shifted to the left and less free energy would

be released. ΔG (kJ/mol) for ATP hydrolysis is lower when $[ATP]/[ADP]$ is low (< 1) than when $[ATP]/[ADP]$ is high. The energy available to the cell from a given $[ATP]$ is lower when the $[ATP]/[ADP]$ ratio falls and greater when it rises. (a) 3.85×10^7 um; [glucose 6-phosphate] = 8.9×10^7 m; no. (Cb) 14 v; because the maximum solubility of glucose is less than 1 M, this is not a reasonable step. (e) 837 ($\Delta G'_{ATP} = -16.7$ kJ/mol); [glucose] = 1.2×10^7 m; yes. (d) No. This would require such high $[P_i]$ that the phosphate salts of divalent cations would precipitate. (e) By directly transferring the phosphoryl group from ATP to glucose, the phosphoryl group transfer potential ("tendency" or "pressure") of ATP is utilized without generating high concentrations of intermediates. The essential part of this transfer is, of course, the enzymatic catalysis. (a) -12.5 kJ/mol (b) -14.6 kJ/mol (a) 3×10^{-6} (b) 68.7 (c) 7.4×10^4 -13 kJ/mol 46.7 kJ/mol Isomerization moves the carbonyl group from C-1 to C-2, setting up a carbon-carbon bond cleavage between C-3 and C-4. Without isomerization, bond cleavage would occur between C-2 and C-3, generating one two-carbon and one four-carbon compound.

17. 18. 19. 20. 21. 22. 23. 24. 25. 26. 27. 28. The mechanism is the same as that of the alcohol dehydrogenase reaction (see Fig. 14-14). The first step is the reverse of an aldol condensation (see the aldolase mechanism, Fig. 14-6); the second step is an aldol condensation (see Fig. 13-4). (a) 46 kJ/mol (b) 46 kg; 68% (c) ATP is synthesized as it is needed, then broken down to ADP and P_i; its concentration is maintained in a steady state. The ATP system is in a dynamic steady state; [ATP] remains constant because the rate of ATP consumption equals its rate of synthesis. ATP consumption involves release of the terminal (γ) phosphoryl group; synthesis of ATP from ADP involves replacement of this phosphoryl group. Hence the terminal phosphate undergoes rapid turnover. In contrast, the central (β) phosphate undergoes only relatively slow turnover. (a) 1.7 kJ/mol (b) Inorganic pyrophosphatase catalyzes the hydrolysis of pyrophosphate and drives the net reaction toward the synthesis of acetyl-CoA. 36 kJ/mol (a) NAD⁺/NADH (b) Pyruvate/lactate (c) Lactate formation (d) —26.1 kJ/mol (e) 3.63×10^4 (a) 1.14 V (b) —220 kJ/mol (c) ~4 (a) —0.35 V (b) —0.820 V (c) —0.29 V In order of increasing tendency: (a), (d), (b), (c) (c) and (d) (a) The lowest-energy, highest-entropy state occurs when the dye concentration is the same in both cells. If a “fish trap” gap junction allowed unidirectional transport, more of the dye would end up in the oligodendrocyte and less in the astrocyte. This would be a higher-energy, lower-entropy state than the starting state, violating the second law of thermodynamics. The model proposed by Robinson et al. requires an impossible spontaneous decrease in entropy. In terms of energy, the model entails a spontaneous change from a lower-energy to a higher-energy state without an energy input—again, thermodynamically impossible. (b) Molecules, unlike fish, do not exhibit directed behavior; they move randomly by Brownian motion. Diffusion results in net movement of molecules from a region of higher concentration to a region of lower concentration simply because it is more likely that a molecule on the high-concentration side will enter the connecting channel. Look at this as a pathway with a rate-limiting step: the narrow end of the channel. The narrower end limits the rate at which molecules pass through because random motion of the molecules is less likely to move them through the smaller cross section. The wide end of the channel does

not act like a funnel for molecules, although it may for fish, because molecules are not “crowded” by the sides of the narrowing funnel as fish would be. The narrow end limits the rate of movement equally in both directions. When the concentrations on both sides are equal, the rates of movement in both directions are equal and there will be no change in concentration. (c) Fish exhibit nonrandom behavior, adjusting their actions in response to the environment. Fish that enter the large opening of the channel tend to move forward because fish have behavior that tends to make them prefer forward movement, and they experience “crowding” as they move through the narrowing channel. It is easy for fish to enter the large opening, but they don’t move out of the trap as readily because they are less likely to enter the small opening. (d) There are many possible explanations, some of which were proposed by the letter-writers who criticized the article. Here are two: (1) The dye could bind to a molecule in the oligodendrocyte. Binding effectively removes the dye from the bulk solvent, so it doesn’t “count” as a solute for thermodynamic considerations yet remains visible in the fluorescence microscope. (2) The dye could be sequestered in a subcellular organelle of the oligodendrocyte, either actively pumped at the expense of ATP or drawn in by its attraction to other molecules in that organelle.

Chapter 14 1. ISA a. 10. 11. 12. 13. 14. 15. Net equation: $\text{Glucose} + 2\text{ATP} \rightarrow 2 \text{glyceraldehyde 3-phosphate} + 2\text{ADP} + 2\text{H}^+$; $\Delta G'^{\circ} = 2.1 \text{ kJ/mol}$. Net equation: $2 \text{Glyceraldehyde 3-phosphate} + 4\text{ADP} + 2\text{P}_i \rightarrow 2 \text{lactate} + 2\text{NAD}^+$; $\Delta G'^{\circ} = -114 \text{ kJ/mol}$. GLUT2 (and GLUT1) is found in liver and is always present in the plasma membrane of hepatocytes. GLUTS3 is always present in the plasma membrane of certain brain cells. GLUT4 is normally sequestered in vesicles in cells of muscle and adipose tissue and enters the plasma membrane only in response to insulin. Thus, liver and brain can take up glucose from blood regardless of insulin level, but muscle and adipose tissue take up glucose only when insulin levels are elevated in response to high blood glucose.

. $\text{CH}_3\text{CHO} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{CH}_3\text{CH}_2\text{OH} + \text{NAD}^+$; $K_{\text{eq}} = 1.45 \times 10^4$. $\Delta G'^{\circ} = -8.6 \text{ kJ/mol}$. (a) “CH₂CH₂OH (b) [3-¹⁴C]glucose or [4-¹⁴C]glucose. Fermentation releases energy, some conserved in the form of ATP but much of it dissipated as heat. Unless the fermenter contents are cooled, the temperature would become high enough to kill the microorganisms. . Soybeans

and wheat contain starch, a polymer of glucose. The microorganisms break down starch to glucose, glucose to pyruvate via glycolysis, and—because the process is carried out in the absence of O_2 (i.e., it is a fermentation)—pyruvate to lactic acid and ethanol. If O_2 were present, pyruvate would be oxidized to acetyl-CoA, then to CO_2 and H_2O . Some of the acetyl-CoA, however, would also be hydrolyzed to acetic acid (vinegar) in the presence of oxygen.

. C-1. This experiment demonstrates the reversibility of the aldolase reaction. The C-1 of glyceraldehyde 3-phosphate is equivalent to C-4 of fructose 1,6-bisphosphate (see Fig. 14-7). The starting glyceraldehyde 3-phosphate must have been labeled at C-1. The C-3 of dihydroxyacetone phosphate becomes labeled through the triose phosphate isomerase reaction, thus giving rise to fructose 1,6-bisphosphate labeled at C-3. No. There would be no anaerobic production of ATP; aerobic ATP production would be diminished only slightly. No. Lactate dehydrogenase is required to recycle NAD^+ from the NADH formed during the oxidation of glyceraldehyde 3-phosphate. The transformation of glucose to lactate occurs when myocytes are low in oxygen, and it provides a means of generating ATP under O_2 -deficient conditions. Because lactate can be oxidized to pyruvate, glucose is not wasted; pyruvate is oxidized by aerobic reactions when O_2 becomes plentiful. This metabolic flexibility gives the organism a greater capacity to adapt to its environment. It rapidly removes the 1,3-bisphosphoglycerate in a favorable subsequent step, catalyzed by phosphoglycerate kinase. (a) 3-Phosphoglycerate is the product. (b) In the presence of arsenate there is no net ATP synthesis under anaerobic conditions. (a) Ethanol fermentation requires 2 mol of P_i per mole of glucose. (b) Ethanol is the reduced product formed during reoxidation of NADH to NAD^+ , and CO_2 is the byproduct of the conversion of pyruvate to ethanol. Yes; pyruvate must be converted to ethanol, to produce a continuous supply of NAD^+ for the oxidation of glyceraldehyde 3-phosphate. Fructose 1,6-bisphosphate accumulates; it is formed as an intermediate in glycolysis. (c) Arsenate replaces P_i in the glyceraldehyde 3-phosphate dehydrogenase reaction to yield an acyl arsenate, which spontaneously hydrolyzes. This

AS-16 Abbreviated Solutions to Problems prevents formation of ATP, but 3-phosphoglycerate continues through the pathway. 16. Dietary niacin is used to synthesize NAD⁺. Oxidations carried out by NAD⁺ are part of cyclic processes, with NAD⁺ as electron carrier (reducing agent); one molecule of NAD⁺ can oxidize many thousands of molecules of glucose, and thus the dietary requirement for the precursor vitamin (niacin) is relatively small. 17. Dihydroxyacetone phosphate + NADH + H⁺ = > glycerol 3-phosphate + NAD⁺ (catalyzed by a dehydrogenase) 18. Galactokinase deficiency: galactose (less toxic); UDP-glucose: galactose 1-phosphate uridylyl deficiency: galactose 1-phosphate (more toxic). 19. The proteins are degraded to amino acids and used for gluconeogenesis. 20. (a) In the pyruvate carboxylase reaction, CO₂ is added to pyruvate, but PEP carboxykinase removes the same CO₂ in the next step. Thus, ¹⁴C is not (initially) incorporated into glucose. (b) (01010 | ne S ic a O > m O > ¢ — OPO214COO- 144COO- 14COO1-4C-Pyruvate Oxaloacetate Phosphoenolpyruvate ae OPOH—C—OH FEOEO ioe 14 Ta oe H—C —OPO214COO- 14COO1,3-Bisphospho- 3-Phospho- 2-Phosphoglycerate glycerate glycerate CHa OPO5 a di TERRE 14C_H — C=O I | O 14CH,OH Glyceraldehyde Dihydroxyacetone 3-phosphate phosphate 2-0;POH;C CH2OPOs HOHE =—¢—0 HO—4 E C—OH H H Fructose 1,6-bisphosphate — — 3,4-4C-Glucose 21. 4 ATP equivalents per glucose molecule 22. Gluconeogenesis would be highly endergonic, and it would be impossible to separately regulate gluconeogenesis and glycolysis. 23. The cell “spends” 1 ATP and 1 GTP in converting pyruvate to PEP. 24. (a), (b), (d) are glucogenic; (c) (e) are not. 25. Consumption of alcohol forces competition for NAD⁺ between ethanol metabolism and gluconeogenesis. The problem is compounded by strenuous exercise and lack of food, because at these times the level of blood glucose is already low. 26. (a) The rapid increase in glycolysis; the rise in pyruvate and NADH results in a rise in lactate. (b) Lactate is transformed to glucose via pyruvate; this is a slower process, because formation of pyruvate is limited by NAD⁺ availability, the LDH equilibrium is in favor of lactate, and conversion of pyruvate to glucose is energy-requiring. (c) The equilibrium for the LDH reaction is in favor of lactate formation. 27. Lactate is transformed to glucose in the liver by gluconeogenesis (see Figs 14-16, 14-17). A

defect in FBPase-1 would prevent entry of lactate into the gluconeogenic pathway in hepatocytes, causing lactate to accumulate in the blood. 28. Succinate is transformed to oxaloacetate, which passes into the cytosol and is converted to PEP by PEP carboxykinase. Two moles of PEP are then required to produce a mole of glucose by the route outlined in Fig. 14-17. 29. If the catabolic and anabolic pathways of glucose metabolism are operating simultaneously, futile cycling of ATP occurs, with extra O₂ consumption. 30. At the very least, accumulation of ribose 5-phosphate would tend to force this reaction in the reverse direction by mass action (see Eqn 13-4). It might also affect other metabolic reactions that involve ribose 5-phosphate as a substrate or product—such as the pathways of nucleotide synthesis. 31. (a) Ethanol tolerance is likely to involve many more genes, and thus the engineering would be a much more involved project. (b) L-Arabinose isomerase (the *araA* enzyme) converts an aldose to a ketose by moving the carbonyl of a nonphosphorylated sugar from C-1 to C-2. No analogous enzyme is discussed in this chapter; all the enzymes described here act on phosphorylated sugars. An enzyme that carries out a similar transformation with phosphorylated sugars is phosphohexose isomerase. L-Ribulokinase (*avaB*) phosphorylates a sugar at C-5 by transferring the γ phosphate from ATP. Many such reactions are described in this chapter, including the hexokinase reaction. L-Ribulose 5-phosphate epimerase (*avaD*) switches the —H and —OH groups on a chiral carbon of a sugar. No analogous reaction is described in the chapter, but it is described in Chapter 20 (see Fig. 20-13). (c) The three *ara* enzymes would convert arabinose to xylulose 5-phosphate by the following pathway: Arabinose $\xrightarrow{\text{AraC}}$ Ribulose 5-phosphate $\xrightarrow{\text{AraB}}$ Xylulose 5-phosphate. (d) The arabinose is converted to xylulose 5-phosphate as in (c), which enters the pathway in Fig. 14-23; the glucose 6-phosphate product is then fermented to ethanol and CO₂s. (e) 6 molecules of arabinose + 6 molecules of ATP are converted to 6 molecules of xylulose 5-phosphate, which feed into the pathway in Fig. 14-23 to yield 5 molecules of glucose 6-phosphate, each of which is fermented to yield 3 ATP (they enter as glucose 6-phosphate, not glucose)—15 ATP in all. Overall, you would expect a yield of 15 ATP — 6 ATP = 9 ATP from the 6 arabinose molecules. The other products are 10 molecules of ethanol and 10 molecules of CO₂s. (f) Given the lower ATP yield, for an amount of

growth (i.e., of available ATP) equivalent to growth without the added genes, the engineered *Z. mobilis* must ferment more arabinose, and thus it produces more ethanol. (g) One way to allow the use of xylose would be to add the genes for two enzymes: an analog of the *avaD* enzyme that converts xylose to ribose by switching the —H and —OH on C-3, and an analog of the *avaB* enzyme that phosphorylates ribose at C-5. The resulting ribose 5-phosphate would feed into the existing pathway. Chapter 15 1. (a) 0.0293 (b) 308 (c) No. Q is much lower than K_{eq} , indicating that the PFK-1 reaction is far from equilibrium in cells; this reaction is slower than the subsequent reactions in glycolysis. Flux through the glycolytic pathway is largely determined by the activity of PFK-1. 2. (a) 1.4×10^{-7} M (b) The physiological concentration (0.023 mM) is 16,000 times the equilibrium concentration; this

10. 11. 12. reaction does not reach equilibrium in the cell. Many reactions in the cell are not at equilibrium. . In the absence of O_2 , the ATP needs are met by anaerobic glucose metabolism (fermentation to lactate). Because aerobic oxidation of glucose produces far more ATP than does fermentation, less glucose is needed to produce the same amount of ATP. . (a) There are two binding sites for ATP: a catalytic site and a regulatory site. Binding of ATP to a regulatory site inhibits PFK-1, by reducing V_{max} or increasing K_m for ATP at the catalytic site. (b) Glycolytic flux is reduced when ATP is plentiful. (c) The graph indicates that increased $[ADP]$ suppresses the inhibition by ATP. Because the adenine nucleotide pool is fairly constant, consumption of ATP leads to an increase in $[ADP]$. The data show that the activity of PFK-1 may be regulated by the $[ATP]/[ADP]$ ratio. . The phosphate group of glucose 6-phosphate is completely ionized at pH 7, giving the molecule an overall negative charge. Because membranes are generally impermeable to electrically charged molecules, glucose 6-phosphate cannot pass from the bloodstream into cells and hence cannot enter the glycolytic pathway and generate ATP. (This is why glucose, once phosphorylated, cannot escape from the cell.) . (a) In muscle: Glycogen breakdown supplies energy (ATP) via glycolysis. Glycogen phosphorylase catalyzes the conversion of stored glycogen to glucose 1-phosphate, which is converted to glucose 6-phosphate, an intermediate in glycolysis. During strenuous activity, skeletal muscle requires large quantities of glucose 6-phosphate. In the liver: Glycogen breakdown maintains a steady level of blood glucose between meals (glucose 6-phosphate is converted to free glucose). (b) In actively working muscle, ATP flux requirements are very high and glucose 1-phosphate must be produced rapidly, requiring a high V_{max} . (a) $[Pi \text{ glucose 1-phosphate}] = 3.3/1$ (b), (c) The value of this ratio in the cell ($> 100:1$) indicates that $[glucose 1-phosphate]$ is far below the equilibrium value. The rate at which glucose 1-phosphate is removed (through entry into glycolysis) is greater than its rate of production (by the glycogen phosphorylase reaction), so metabolite flow is from glycogen to glucose 1-phosphate. The glycogen phosphorylase reaction is probably the regulatory step in glycogen breakdown. . (a) increases (b) decreases (c) increases . Resting: $[ATP]$ high; $[AMP]$ low; $[acetyl-CoA]$ and $[citrate]$ intermediate. Running: $[ATP]$ intermediate; $[AMP]$ high; $[acetyl-$

CoA] and [citrate] low. Glucose flux through glycolysis increases during the anaerobic sprint because (1) the ATP inhibition of glycogen phosphorylase and PFK-1 is partially relieved, (2) AMP stimulates both enzymes, and (3) lower citrate and acetyl-CoA levels relieve their inhibitory effects on PFK-1 and pyruvate kinase, respectively. The migrating bird relies on the highly efficient aerobic oxidation of fats, rather than the anaerobic metabolism of glucose used by a sprinting rabbit. The bird reserves its muscle glycogen for short bursts of energy during emergencies. Case A: (D), (8); Case B: (c), (3); Case C: (h), (4); Case D: (d), (6) (a) (1)

Adipose: fatty acid synthesis slower. (2) Muscle: glycolysis, fatty acid synthesis, and glycogen synthesis slower. (3) Liver: glycolysis faster; gluconeogenesis, glycogen synthesis, and fatty acid synthesis slower; pentose phosphate pathway unchanged. (b) (1) Adipose and (3) liver: fatty acid synthesis slower because lack of insulin results in inactive acetyl-CoA carboxylase, the first enzyme of fatty acid synthesis. Glycogen synthesis inhibited by cAMP-dependent phosphorylation (thus activation) of glycogen synthase. (2) Muscle: glycolysis slower because GLUT4 is inactive, so glucose uptake is inhibited. (3) Liver: glycolysis slower because the bifunctional PFK-2/ FBPase-2 is converted to the form with active FBPase-2, 13. 14. 15. 16. 17. Abbreviated Solutions to Problems AS-17 decreasing [fructose 2,6-bisphosphate], which allosterically stimulates phosphofructokinase and inhibits FBPase-1; this also accounts for the stimulation of gluconeogenesis. (a) elevated (b) elevated (c) elevated (a) PKA cannot be activated in response to glucagon or epinephrine, and glycogen phosphorylase is not activated. (b) PP1 remains active, allowing it to dephosphorylate glycogen synthase (activating it) and glycogen phosphorylase (inhibiting it). Cc) Phosphorylase remains phosphorylated (active), increasing the breakdown of glycogen. (d) Gluconeogenesis cannot be stimulated when blood glucose is low, leading to dangerously low blood glucose during periods of fasting. The drop in blood glucose triggers release of glucagon by the pancreas. In the liver, glucagon activates glycogen phosphorylase by stimulating its cAMP-dependent phosphorylation and stimulates gluconeogenesis by lowering [fructose 2,6-bisphosphate], thus stimulating FBPase-1. (a) Reduced capacity to mobilize glycogen; lowered blood glucose between meals (b) Reduced capacity to lower blood glucose after a carbohydrate meal; elevated blood glucose Cc) Reduced fructose

2,6-bisphosphate (F26BP) in liver, stimulating glycolysis and inhibiting gluconeogenesis (d) Reduced F26BP, stimulating gluconeogenesis and inhibiting glycolysis (e) Increased uptake of fatty acids and glucose; increased oxidation of both (f) Increased conversion of pyruvate to acetyl-CoA; increased fatty acid synthesis.

(a) Given that each particle contains about 55,000 glucose residues, the equivalent free glucose concentration would be $55,000 \times 0.01 \mu\text{M} = 550 \text{ mM}$, or 0.55 M . This would present a serious osmotic challenge for the cell! (Body fluids have a substantially lower osmolarity.) (b) The lower the number of branches, the lower the number of free ends available for glycogen phosphorylase activity, and the slower the rate of glucose release. With no branches, there would be just one site for phosphorylase to act. (c) The outer tier of the particle would be too crowded with glucose residues for the enzyme to gain access to cleave bonds and release glucose. (d) The number of chains doubles in each succeeding tier: tier 1 has one chain (2^0), tier 2 has two (2^1), tier 3 has four (2^2), and so on. Thus, for t tiers, the number of chains in the outermost tier, C_t , is 2^t . (e) The total number of chains is $2^0 + 2^1 + 2^2 + \dots + 2^{t-1} = 2^t - 1$. Each chain contains g glucose molecules, so the total number of glucose molecules, G_t , is $g(2^t - 1)$. (f) Glycogen phosphorylase can release all but four of the glucose residues in a chain of length g . Therefore, from each chain in the outer tier it can release $(g - 4)$ glucose molecules. Given that there are 2^{t-1} chains in the outer tier, the number of glucose molecules the enzyme can release, G_{pr} , is $(g - 4)(2^{t-1})$. (g) The volume of a sphere is $\frac{4}{3}\pi r^3$. In this case, r is the thickness of one tier times the number of tiers, or $(0.12g + 0.35)t \text{ nm}$. Thus $V_t = \frac{4}{3}\pi (0.12g + 0.35)^3 t^3 \text{ nm}^3$. (h) You can show algebraically that the value of g that maximizes f is independent of t . Choosing $t = 3$:

| | C_t | G_t | G_{pr} | S | f |

AS-18 Abbreviated Solutions to Problems The optimum value of g . (i.e., at maximum f) is 13. In nature, g varies from 12 to 14, which corresponds to f values very close to the optimum. If you choose another value for t , the numbers will differ but the optimal g , will still be 13. Chapter 16

TPP: thiazolium ring adds to a carbon of pyruvate, then stabilizes the resulting carbanion by acting as an

electron sink. Lipoic acid: oxidizes pyruvate to level of acetate (acetylCoA), and activates acetate as a thioester. CoA-SH: activates acetate as thioester. FAD: oxidizes lipoic acid. NAD⁺: oxidizes FAD. . Lack of TPP inhibits pyruvate dehydrogenase; pyruvate accumulates. . Oxidative decarboxylation; NAD⁺ or NADP⁺; α-ketoglutarate dehydrogenase . Oxygen consumption is a measure of the activity of the first two stages of cellular respiration: glycolysis and the 10. 11. 12. 13. 14. 15. 16. 17. 18. 19. 20. 21. 22. 23. citric acid cycle. The addition of oxaloacetate or malate stimulates the citric acid cycle and thus stimulates respiration. The added oxaloacetate or malate serves a catalytic role, because it is regenerated in the latter part of the citric acid cycle. (a) 5.6×10^7 (b) 1.1×10^{18} m (c) 28 molecules ADP (or GDP), P_i, CoA-SH, TPP, NAD⁺; not lipoic acid, which is covalently attached to the isolated enzymes that use it The flavin nucleotides, FMN and FAD, would not be synthesized. Because FAD is required in the citric acid cycle, flavin deficiency would strongly inhibit the cycle. Oxaloacetate might be withdrawn for aspartate synthesis or for gluconeogenesis. Oxaloacetate is replenished by the anaplerotic reactions catalyzed by PEP carboxykinase, PEP carboxylase, malic enzyme, or pyruvate carboxylase (see Fig. 16-16). The terminal phosphoryl group in GTP can be transferred to ADP in a reaction catalyzed by nucleoside diphosphate kinase, with an equilibrium constant of 1.0: $\text{GTP} + \text{ADP} \rightarrow \text{GDP} + \text{ATP}$ (a) $\text{OOC}-\text{CH}_2-\text{CH}_2-\text{COO}^-$ (succinate) (b) Malonate is a competitive inhibitor of succinate dehydrogenase. (c) A block in the citric acid cycle stops NADH formation, which stops electron transfer, which stops respiration. (d) A large excess of succinate (substrate) overcomes the competitive inhibition. (a) Add uniformly labeled [¹⁴C]glucose and check for the release of 4CO₂. (b) Equally distributed in C-2 and C-3 of oxaloacetate; an infinite number Oxaloacetate equilibrates with succinate, in which C-1 and C-4 are equivalent. Oxaloacetate derived from succinate is labeled at C-1 and C-4, and the PEP derived from it has label at C-1, which gives rise to C-3 and C-4 of glucose. (a) C-1 (b) C-3 (c) C-3 (d) C-2 (methyl group) (e) C-4 (f) C-4 (g) equally distributed in C-2 and C-3 Thiamine is required for the synthesis of TPP, a prosthetic group in the pyruvate dehydrogenase and α-ketoglutarate dehydrogenase complexes. A thiamine deficiency reduces the activity of these enzyme complexes and causes the observed accumulation of precursors. No. For every two carbons that enter as

acetate, two leave the cycle as CO₂s; thus there is no net synthesis of oxaloacetate. Net synthesis of oxaloacetate occurs by the carboxylation of pyruvate, an anaplerotic reaction. Yes, the citric acid cycle would be inhibited. Oxaloacetate is present at relatively low concentrations in mitochondria, and removing it for gluconeogenesis would tend to shift the equilibrium for the citrate synthase reaction toward oxaloacetate. (a) Inhibition of aconitase (b) Fluorocitrate; competes with citrate; by a large excess of citrate (c) Citrate and fluorocitrate are inhibitors of PFK-1. (d) All catabolic processes necessary for ATP production are shut down. Glycolysis: $\text{Glucose} + 2\text{P}_i + 2\text{ADP} + 2\text{NAD}^+ \rightarrow 2 \text{pyruvate} + 2\text{ATP} + 2\text{NADH} + 2\text{H}^+ + 2\text{H}_2\text{O}$ Pyruvate carboxylase reaction: $2 \text{Pyruvate} + 2\text{CO}_2 + 2\text{ATP} + 2\text{H}_2\text{O} \rightarrow 2 \text{oxaloacetate} + 2\text{ADP} + 2\text{P}_i + 4\text{H}^+$ Malate dehydrogenase reaction: $2 \text{Oxaloacetate} + 2\text{NADH} + 2\text{H}^+ \rightarrow 2 \text{-malate} + 2\text{NAD}^+$ This recycles nicotinamide coenzymes under anaerobic conditions. The overall reaction is $\text{Glucose} + 2\text{CO}_2 \rightarrow 2 \text{L-malate} + 4\text{H}^+$ This produces four H⁺ per glucose, increasing the acidity and thus the tartness of the wine.

24. 25 26. 27. 28. 29 30. 31. 32. 33. 34. 35. 36. Net reaction: $2 \text{ Pyruvate} + \text{ATP} + 2\text{NAD}^* + \text{H}_2\text{O} \rightarrow \alpha\text{-ketoglutarate} + \text{CO}_2 + \text{ADP} + \text{P}_i + 2\text{NADH} + 3\text{H}^+$. The cycle participates in catabolic and anabolic processes. For example, it generates ATP by substrate oxidation, but also provides precursors for amino acid synthesis (see Fig. 16-16). (a) decreases (b) increases (c) decreases (a) Citrate is produced through the action of citrate synthase on oxaloacetate and acetyl-CoA. Citrate synthase can be used for net synthesis of citrate when (1) there is a continuous influx of new oxaloacetate and acetyl-CoA and (2) isocitrate synthesis is restricted, as in a medium low in Fe^{2+} . Aconitase requires Fe^{2+} , so an Fe^{2+} -restricted medium restricts the synthesis of aconitase. (b) $\text{Sucrose} + \text{H}_2\text{O} \rightarrow \text{glucose} + \text{fructose}$ $\text{Glucose} + 2\text{P}_i + 2\text{ADP} + 2\text{NAD}^* \rightarrow 2 \text{ pyruvate} + 2\text{ATP} + 2\text{NADH} + 2\text{H}^+ + 2\text{H}_2\text{O}$ $\text{Fructose} + 2\text{P}_i + 2\text{ADP} + 2\text{NAD}^* \rightarrow 2 \text{ pyruvate} + 2\text{ATP} + 2\text{NADH} + 2\text{H}^+ + 2\text{H}_2\text{O}$ $2 \text{ Pyruvate} + 2\text{NAD}^* + 2\text{CoA} \rightarrow 2 \text{ acetyl-CoA} + 2\text{NADH} + 2\text{H}^+ + 2\text{CO}_2$ $2\text{CoA} + 2\text{ATP} + 2\text{H}_2\text{O} \rightarrow 2 \text{ oxaloacetate} + 2\text{ADP} + 2\text{P}_i + 4\text{H}^+$ $2 \text{ Acetyl-CoA} + 2 \text{ oxaloacetate} + 2\text{H}_2\text{O} \rightarrow 2 \text{ citrate} + 2\text{CoA}$ The overall reaction is $\text{Sucrose} + \text{H}_2\text{O} + 2\text{P}_i + 2\text{ADP} + 6\text{NAD}^* \rightarrow 2 \text{ citrate} + 2\text{ATP} + 6\text{NADH} + 10\text{H}^+$ (c) The overall reaction consumes NAD^* . Because the cellular pool of this oxidized coenzyme is limited, it must be recycled by the electron-transfer chain with consumption of O_2 . Consequently, the overall conversion of sucrose to citric acid is an aerobic process and requires molecular oxygen. $2 \text{ Pyruvate} + \text{Succinyl-CoA}$ is an intermediate of the citric acid cycle; its accumulation signals reduced flux through the cycle, calling for reduced entry of acetyl-CoA into the cycle. Citrate synthase, by regulating the primary oxidative pathway of the cell, regulates the supply of NADH and thus the flow of electrons from NADH to O_2 . Fatty acid catabolism increases [acetyl-CoA], which stimulates pyruvate carboxylase. The resulting increase in [oxaloacetate] stimulates acetyl-CoA consumption by the citric acid cycle, and [citrate] rises, inhibiting glycolysis at the level of PFK-1. In addition, increased [acetyl-CoA] inhibits the pyruvate dehydrogenase complex, slowing the utilization of pyruvate from glycolysis. Oxygen is needed to recycle NAD^* from the NADH produced by the oxidative reactions of the citric acid cycle. Reoxidation of NADH occurs during mitochondrial oxidative phosphorylation. Increased $[\text{NADH}]/[\text{NAD}^*]$ inhibits the

citric acid cycle by mass action at the three NAD⁺-reducing steps; high [NADH] shifts equilibrium toward NAD⁺. Toward citrate; ΔG for the citrate synthase reaction under these conditions is about -8 kJ/mol. Steps ④ and ⑤ are essential in the reoxidation of the enzyme's reduced lipoamide cofactor. The citric acid cycle is so central to metabolism that a serious defect in any cycle enzyme would probably be lethal to the embryo. The first enzyme in each path is under reciprocal allosteric regulation. Inhibition of one path shunts isocitrate into the other path. (a) The only reaction in muscle tissue that consumes significant amounts of oxygen is cellular respiration, so O₂ consumption is a good proxy for respiration. (b) Freshly prepared muscle tissue contains some residual glucose; O₂ consumption is due to oxidation of this glucose. (c) Yes. Because the amount of O consumed increased when citrate or 1-phosphoglycerol was added, both can serve as substrate. Abbreviated Solutions to Problems AS-19 for cellular respiration in this system. (d)

Experiment I: Citrate is causing much more O₂ consumption than would be expected from its complete oxidation. Each molecule of Citrate seems to be acting as though it were more than one molecule. The only possible explanation is that each molecule of citrate functions more than once in the reaction—which is how a catalyst operates. Experiment II: The key is to calculate the excess O₂ consumed by each sample compared with the control (sample 1).

| Substrate(s) | pL O ₂ | Excess | uL Sample | added | absorbed | O ₂ consumed |
|--------------|-------------------|--------|-----------|--------------------------------|---|-------------------------|
| 1 | No extra | 342 | 0 | 0.3 mL 0.2 M 1-phosphoglycerol | 757 | 415 |
| 2 | 3 | 0.15 | | | | |
| 3 | 0.02 M citrate | 431 | 89 | 4 | 0.3 mL 0.2 M 1-phosphoglycerol + 0.15 mL 0.02 M citrate | 1,385 |
| 4 | | | | | | 1,043 |

If both citrate and 1-phosphoglycerol were simply substrates for the reaction, you would expect the excess O₂ consumption by sample 4 to be the sum of the individual excess consumptions by samples 2 and 3 (415 uL + 89 uL = 504 uL). However, the excess consumption when both substrates are present is roughly twice this amount (1,043 uL). Thus citrate increases the ability of the tissue to metabolize 1-phosphoglycerol. This behavior is typical of a catalyst. Both experiments (I and II) are required to make this case convincing. Based on experiment I only, citrate is somehow accelerating the reaction, but it is not clear whether it acts by helping substrate metabolism or by some other mechanism. Based on experiment II only, it is not clear which molecule is the catalyst, citrate or 1-phosphoglycerol. Together, the experiments show that citrate is

acting as a “catalyst” for the oxidation of 1-phosphoglycerol. (e) Given that the pathway can consume citrate (see sample 3), if citrate is to act as a catalyst it must be regenerated. If the set of reactions first consumes then regenerates citrate, it must be a circular rather than a linear pathway. (f) When the pathway is blocked at α -ketoglutarate dehydrogenase, citrate is converted to α -ketoglutarate but the pathway goes no further. Oxygen is consumed by reoxidation of the NADH produced by isocitrate dehydrogenase. (g) Citrate Glucose $\rightarrow$? ? ? α -Ketoglutarate Succinate Oxaloacetate Fumarate Malonate This differs from Fig. 16-7 in that it does not include cisaconitate and isocitrate (between citrate and α -ketoglutarate), or succinyl-CoA, or acetyl-CoA. (h) Establishing a quantitative conversion was essential to rule out a branched or other, more complex pathway. Chapter 17 1. The fatty acid portion; the carbons in fatty acids are more reduced than those in glycerol. 2. (a) 4.0×10^6 kJ (9.6×10^6 kcal) (b) 48 days (c) 0.48 lb/day 3. The first step in fatty acid oxidation is analogous to the conversion of succinate to fumarate; the second step, to the conversion of fumarate to malate; the third step, to the conversion of malate to oxaloacetate. 4. 8 cycles; the last releases 2 acetyl-CoA.

AS-20 Abbreviated Solutions to Problems 10. 11. 12. 13. 14. 15. 16. 17. 18. 19. . (a) $R-COO^{\text{TM}} + \text{ATP} \rightarrow \text{acyl-AMP} + \text{PP}$, $\text{Acyl-AMP} + \text{CoA} \rightarrow \text{acyl-CoA} + \text{AMP}$ (Cb) Irreversible hydrolysis of PP; to 2P; by cellular inorganic pyrophosphatase . cis-A®-Dodecanoyl-CoA; it is converted to cis-A?-dodecanoylCoA, then B-hydroxydodecanoyl-CoA. . 4 acetyl-CoA and 1 propionyl-CoA . Yes. Some of the tritium is removed from palmitate during the dehydrogenation reactions of B oxidation. The removed tritium appears as tritiated water. . Fatty acyl groups condensed with CoA in the cytosol are first transferred to carnitine, releasing CoA, then transported into the mitochondrion, where they are again condensed with CoA. The cytosolic and mitochondrial pools of CoA are thus kept separate, and no radioactive CoA from the cytosolic pool enters the mitochondrion. (a) In the pigeon, B oxidation predominates; in the pheasant, anaerobic glycolysis of glycogen predominates. (b) Pigeon muscle would consume more Os. (c) Fat contains more energy per gram than glycogen does. In addition, the anaerobic breakdown of glycogen is limited by the tissue's tolerance to lactate buildup. Thus the pigeon, operating on the oxidative catabolism of fats, is the long-distance flyer. (d) These enzymes are the regulatory enzymes of their respective pathways and thus limit ATP production rates. Malonyl-CoA would no longer inhibit fatty acid entry into the mitochondrion and £ oxidation, so there might be a futile cycle of simultaneous fatty acid synthesis in the cytosol and fatty acid breakdown in mitochondria. (a) The carnitine-mediated entry of fatty acids into mitochondria is the rate-limiting step in fatty acid oxidation. Carnitine deficiency slows fatty acid oxidation; added carnitine increases the rate. (b) All increase the metabolic need for fatty acid oxidation. (c) Carnitine deficiency might result from a deficiency of lysine, its precursor, or from a defect in one of the enzymes in the biosynthesis of carnitine. Oxidation of fats releases metabolic water; 1.4 L of water per kg of tripalmitoylglycerol (ignores the small contribution of glycerol to the mass). The bacteria can be used to completely oxidize hydrocarbons to CO; and H₂O. However, contact between hydrocarbons and bacterial enzymes may be difficult to achieve. Bacterial nutrients such as nitrogen and phosphorus may be limiting and inhibit growth. (a) M, 136; phenylacetic acid (b) Even Because the mitochondrial pool of CoA is small, CoA must be recycled from

acetyl-CoA via the formation of ketone bodies. This allows the operation of the β -oxidation pathway, necessary for energy production. (a) Glucose yields pyruvate via glycolysis, and pyruvate is the main source of oxaloacetate. Without glucose in the diet, [oxaloacetate] drops and the citric acid cycle slows. (b) Oddnumbered; propionate conversion to succinyl-CoA provides intermediates for the citric acid cycle and four-carbon precursors for gluconeogenesis. For the odd-chain heptanoic acid, 6 oxidation produces propionyl-CoA, which can be converted in several steps to oxaloacetate, a starting material for gluconeogenesis. The evenchain fatty acid cannot support gluconeogenesis, because it is entirely oxidized to acetyl-CoA. β Oxidation of ω -fluorooleate forms fluoroacetyl-CoA, which enters the citric acid cycle and produces fluorocitrate, a powerful inhibitor of aconitase. Inhibition of aconitase shuts down the citric acid cycle. Without reducing equivalents from the citric acid cycle, oxidative phosphorylation (ATP synthesis) is fatally slowed. 20. 21. 22. 23. 24. 25. 26. 27. 28. 29. Elaidoyl-CoA carnitine acyltransferase I — > (outside) elaidoyl-carnitine carnitine acyltransferase II . . cool (inside) 8 z E thioest 5-trans-tetradecenoyl-CoA thioesterase, Ser to Ala: blocks β oxidation in mitochondria. Ser to Asp: blocks fatty acid synthesis, stimulates β oxidation. Response to glucagon or epinephrine would be prolonged, giving a greater mobilization of fatty acids in adipocytes. Enz-FAD, having a more positive standard reduction potential, is a better electron acceptor than NAD^+ , and the reaction is driven in the direction of fatty acyl-CoA oxidation. This more favorable equilibrium is obtained at the cost of 1 ATP; only 1.5 ATP are produced per FADH, oxidized in the respiratory chain (vs. 2.5 per NADH). 9 turns; arachidic acid, a 20-carbon saturated fatty acid, yields 10 molecules of acetyl-CoA, the last two formed in the ninth turn. See Fig. 17-12. [3- ^{14}C]Succinyl-CoA is formed, which gives rise to oxaloacetate labeled at C-2 and C-3. Phytanic acid — pristanic acid — propionyl-CoA —> — — succinylCoA —> succinate — fumarate — malate. All malate carbons would be labeled, but C-1 and C-4 would have only half as much label as C-2 and C-3. ATP hydrolysis in the energy-requiring reactions of a cell takes up water in the reaction $\text{ATP} + \text{H}_2\text{O} \rightarrow \text{ADP} + \text{P}_i$; thus, in the steady state, there is no net production of H_2O . Methylmalonyl-CoA mutase requires the cobalt-containing cofactor formed from vitamin B₁₂. Mass lost per day is about 0.66 kg, or about 140 kg in 7

months. Ketosis could be avoided by degradation of nonessential body proteins to supply amino acid skeletons for gluconeogenesis.

(a) Fatty acids are converted to their CoA derivatives by enzymes in the cytoplasm; the acyl-CoAs are then imported into mitochondria for oxidation. Given that the researchers were using isolated mitochondria, they had to use CoA derivatives. (b) Stearoyl-CoA was rapidly converted to 9 acetylCoA by the β -oxidation pathway. All intermediates reacted rapidly and none were detectable at significant levels. (c) Two rounds. Each round removes two carbon atoms, thus two rounds convert an 18-carbon to a 14-carbon fatty acid and 2 acetyl-CoA. (d) The K_m is higher for the trans isomer than for the cis, so a higher concentration of trans isomer is required for the same rate of breakdown. Roughly speaking, the trans isomer binds less well than the cis, probably because differences in shape, even though not at the target site for the enzyme, affect substrate binding to the enzyme. (e) The substrate for LCAD/VLCAD builds up differently, depending on the particular substrate; this is expected for the rate-limiting step in a pathway. (f) The kinetic parameters show that the trans isomer is a poorer substrate than the cis for LCAD, but there is little difference for VLCAD. Because it is a poorer substrate, the trans isomer accumulates to higher levels than the cis. (g) One possible pathway is shown below (indicating “inside” and “outside” mitochondria). elaidoyl-carnitine transport (outside) elaidoyl-CoA 2 rounds of β -oxidation eee (inside) (inside) (inside) 5-trans-tetradecanoic acid (outside) Ch) It is correct insofar as trans fats are broken down less efficiently than cis fats, and thus trans fats may “leak” out of mitochondria. It is incorrect to say that trans fats are not broken down by cells; they are broken down, but at a slower rate than cis fats. 5-trans-tetradecanoic acid diffusion —>

Chapter 18 1. 1 (a) $\sim\text{OOC}-\text{CH}_2-\text{C}-\text{COO}\sim$ Oxaloacetate (0) | (b) $\sim\text{OOC}-\text{CH}_2-\text{CH}_2-\text{C}-\text{COO}\sim$ a-Ketoglutarate I (c) $\text{CH}_3-\text{C}-\text{COO}\sim$ Pyruvate ji (d) (Non, $-\text{C}-\text{COO}\sim$ 7 Phenylpyruvate . This is a coupled-reaction assay. The product of the slow transamination (pyruvate) is rapidly consumed in the subsequent “indicator reaction” catalyzed by lactate dehydrogenase, which consumes NADH. Thus the rate of disappearance of NADH is a measure of the rate of the aminotransferase reaction. The indicator reaction is monitored by observing the decrease in absorption of NADH at 340 nm with a spectrophotometer. . Alanine and glutamine play special roles in the transport of amino groups from muscle and from other nonhepatic tissues, respectively, to the liver. . No. The nitrogen in alanine can be transferred to oxaloacetate via transamination, to form aspartate. . 15 mol of ATP per mole of lactate; 13 mol of ATP per mole of alanine, when nitrogen removal is included . (a) Fasting resulted in low blood glucose; subsequent administration of the experimental diet led to rapid catabolism of glucogenic amino acids. (b) Oxidative deamination caused the rise in NH_4^+ levels; the absence of arginine (an intermediate in the urea cycle) prevented conversion of NH_4^+ to urea; arginine is not synthesized in sufficient quantities in the cat to meet the needs imposed by the stress of the experiment. This suggests that arginine is an essential amino acid in the cat’s diet. (c) Ornithine is converted to arginine by the urea cycle. . $\text{H}_2\text{O} + \text{glutamate} + \text{NAD}^+ \rightarrow \text{a-ketoglutarate} + \text{NH}_4^+ + \text{NADH} + \text{H}^+$ $\text{NH}_4^+ + 2\text{ATP} + \text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{carbamoyl phosphate} + 2\text{ADP} + \text{P}_i$ $+ 3\text{H}^+$ $\text{Carbamoyl phosphate} + \text{ornithine} \rightarrow \text{citrulline} + \text{P}_i$ $+ \text{H}^+$ $\text{Citrulline} + \text{aspartate} + \text{ATP} \rightarrow \text{argininosuccinate} + \text{AMP} + \text{PP}_i$ $+ \text{H}^+$ $\text{Argininosuccinate} \rightarrow \text{arginine} + \text{fumarate}$ $\text{Fumarate} + \text{H}_2\text{O} \rightarrow \text{malate}$ $\text{Malate} + \text{NAD}^+ \rightarrow \text{oxaloacetate} + \text{NADH} + \text{H}^+$ $\text{Oxaloacetate} + \text{glutamate} \rightarrow \text{aspartate} + \text{a-ketoglutarate}$ $\text{Arginine} + \text{H}_2\text{O} \rightarrow \text{urea} + \text{ornithine}$ 2 $\text{Glutamate} + \text{CO}_2 + 4\text{H}_2\text{O} + 2\text{NAD}^+ \rightarrow 2 \text{a-ketoglutarate} + 2\text{NADH} + 3\text{ATP} + 7\text{H}^+ + \text{urea} + 2\text{ADP} + \text{AMP} + \text{PP}_i + 2\text{P}_i$ d) Additional reactions that need to be considered: $\text{AMP} + \text{ATP} \rightarrow 2\text{ADP}$ (2) $\text{O} + 8\text{H}^+ + 2\text{NADH} + 6\text{ADP} + 6\text{P}_i \rightarrow 2\text{NAD}^+ + 6\text{ATP} + 8\text{H}_2\text{O}$ (8) $\text{HO} + \text{PP}_i \rightarrow 2\text{P}_i + \text{H}^+$ (4) Summing equations (1) through (4), 2 $\text{Glutamate} + \text{CO}_2 + \text{O} + 2\text{ADP} + 2\text{P}_i \rightarrow 2 \text{a-ketoglutarate} + \text{urea} + 3\text{H}_2\text{O} + 2\text{ATP}$. The second amino group introduced into urea is transferred from aspartate, which is generated during the

transamination of glutamate to oxaloacetate, a reaction catalyzed by aspartate aminotransferase. Approximately one-half of all the amino groups excreted as urea must pass through the aspartate aminotransferase reaction, making this the most highly active aminotransferase. . (a) A person on a diet consisting only of protein must use amino acids as the principal source of metabolic fuel. Because the catabolism of amino acids requires the removal of nitrogen as urea, the process consumes abnormally large quantities of water to dilute and excrete the urea in the urine. Furthermore, electrolytes in the “liquid protein” must be diluted with water and excreted. If the daily water loss through the kidney is not balanced by a sufficient water intake, a net loss of body water results. (b) When considering the nutritional benefits of protein, one must keep in mind the total amount of amino acids needed for protein synthesis and the distribution of amino acids in the dietary protein. Gelatin contains a nutritionally unbalanced distribution of amino acids. As large amounts of gelatin are ingested and the excess amino acids are catabolized, the capacity of the urea cycle may be exceeded, leading to ammonia toxicity. This is further complicated by the dehydration that may result from excretion of large quantities of urea. A combination of these two factors could produce coma and death. Lysine and leucine (a) Phenylalanine hydroxylase; a low-phenylalanine diet (b) The normal route of phenylalanine metabolism via hydroxylation to tyrosine is blocked, and phenylalanine accumulates. (c) Phenylalanine is transformed to phenylpyruvate by transamination, and then to phenyllactate by reduction. The transamination reaction has an equilibrium constant of 1.0, and phenylpyruvate is formed in significant amounts when phenylalanine accumulates. (d) Because of the deficiency in production of tyrosine, which is a precursor of melanin, the pigment normally present in hair. Catabolism of the carbon skeletons of valine, methionine, and isoleucine is impaired because a functional methylmalonyl-CoA mutase (a coenzyme B₁₂ enzyme) is absent. The physiological effects of loss of this enzyme are described in Table 18-2 and Box 18-2. The vegan diet lacks vitamin B₁₂, leading to the increase in homocysteine and methylmalonate (reflecting the deficiencies in methionine synthase and methylmalonic acid mutase, respectively) in individuals on the diet for several years. Dairy products provide some vitamin B₁₂ in the

lactovegetarian diet. The genetic forms of pernicious anemia generally arise as a result of defects in the pathway that mediates absorption of dietary vitamin B₁₂, (see Box 17-2). Because dietary supplements are not absorbed in the intestine, these conditions are treated by injecting supplementary B₁₂ directly into the bloodstream. The mechanism is identical to that for serine dehydratase (see Fig. 18-20a) except that the extra methyl group of threonine is retained, yielding α-ketobutyrate instead of pyruvate.

A likely mechanism is: H OH Paw | | | "00C—C—C-H_ ž + HO p | | N *NH, H | r Ear Serine CH; N N | C—H | / / 'i HO CS / € CH; N CH, N i; Glycine TONG ad H + *NH Lys -00C—C—H Hi bey "NH, *NH ive SH HO | oe C DAN HO De + f + CH, `N CH, `N PLP The formaldehyde (HCHO) produced in the second step reacts rapidly with tetrahydrofolate at the enzyme active site to produce N*,N"-methylenetetrahydrofolate (see Fig. 18-17). 19. (a) Transamination; no analogies; PLP. (b) Oxidative decarboxylation; analogous to oxidative decarboxylation of pyruvate to acetyl-CoA prior to entry into the citric acid cycle, and of α -ketoglutarate to succinyl-CoA in the citric acid cycle; NAD⁺, FAD, lipoate, and TPP. (c) Dehydrogenation (oxidation); analogous to dehydrogenation of succinate to fumarate in the citric acid cycle, and of fatty acyl-CoA to enoyl-CoA in β oxidation; FAD. (d) Carboxylation; no analogies in citric acid cycle or β oxidation; ATP and biotin. (e) Hydration; analogous to hydration of fumarate to malate in the citric acid cycle, and of enoyl-CoA to 3-hydroxyacyl-CoA in β oxidation; no cofactors. (f) Reverse aldol reaction; analogous Lye to reverse of citrate synthase reaction in the citric acid cycle; no cofactors 20. (a) Leucine; valine; isoleucine (b) Cysteine (derived from cystine). If cysteine were decarboxylated as shown in Fig. 18-6, it would yield H₂N—CH₂—CH₂—SH, which could be oxidized to taurine. (c) The January 1957 blood shows significantly elevated levels of isoleucine, leucine, methionine, and valine; the January 1957 urine, significantly elevated isoleucine, leucine, taurine, and valine. (d) All patients had high levels of isoleucine, leucine, and valine in both blood and urine, suggesting a defect in the breakdown of these amino acids. Given that the urine also contained high levels of the keto forms of these three amino acids, the block in the pathway must occur after deamination but before dehydrogenation (as

shown in Fig. 18-28). (e) The model does not explain the high levels of methionine in blood and taurine in urine. The high taurine levels may be due to the death of brain cells during the end stage of the disease. However, the reason for high levels of methionine in blood are unclear; the pathway of methionine degradation is not linked with the degradation of branched-chain amino acids. Increased methionine could be a secondary effect of buildup of the other amino acids. It is important to keep in mind that the January 1957 samples were from an individual who was dying, so comparing blood and urine results with those of a healthy individual may not be appropriate. (f) The following information is needed (and was eventually obtained by other workers): (1) The dehydrogenase activity is significantly reduced or missing in individuals with maple syrup urine disease. (2) The disease is inherited as a single-gene defect. (3) The defect occurs in a gene encoding all or part of the dehydrogenase. (4) The genetic defect leads to production of inactive enzyme.

Chapter 19

- Reaction (1): (a), (d) NADH; (b), (e) E-FMN; (c) NAD^+/NADH and $\text{E-FMN}/\text{FMNH}$, Reaction (2): (a), (d) E-FMNH ; (b), (e) Fe^{2+} ; (c) $\text{E-FMN}/\text{FMNH}$ and $\text{Fe}^{2+}/\text{Fe}^{3+}$ Reaction (3): (a), (d) Fe^{2+} ; (b), (e) Q; (c) $\text{Fe}^{3+}/\text{Fe}^{2+}$ and Q/QH .
- The side chain makes ubiquinone soluble in lipids and allows it to diffuse in the semifluid membrane.
- From the difference in standard reduction potential (E'°) for each pair of half-reactions, one can calculate $\Delta G'^{\circ}$. The oxidation of succinate by FAD is favored by the negative standard free-energy change ($\Delta G'^{\circ} = -3.7 \text{ kJ/mol}$). Oxidation by NAD^+ would require a large, positive, standard free-energy change ($\Delta G'^{\circ} = 68 \text{ kJ/mol}$).
- (a) All carriers reduced; CN^- blocks the reduction of Os catalyzed by cytochrome oxidase. (b) All carriers reduced; in the absence of Os, the reduced carriers are not reoxidized. (c) All carriers oxidized. (d) Early carriers more reduced; later carriers more oxidized.
- (a) Inhibition of NADH dehydrogenase by rotenone decreases the rate of electron flow through the respiratory chain, which in turn decreases the rate of ATP production. If this reduced rate is unable to meet the organism's ATP requirements, the organism dies. (b) Antimycin A strongly inhibits the oxidation of Q in the respiratory chain, reducing the rate of electron transfer and leading to the consequences described in (a). (c) Because antimycin A blocks all electron flow to oxygen, it is a more potent poison than rotenone, which blocks electron flow from NADH but not from FADHs.
- (a)

The rate of electron transfer necessary to meet the ATP demand increases, and thus the P/O ratio decreases. (b) High concentrations of uncoupler produce P/O ratios near zero. The P/O ratio decreases, and more fuel must be oxidized to generate the same amount of ATP. The extra heat released by this oxidation raises the body temperature. (c) Increased activity of

10. 11. 12. 13. 14. 15. 16. 17. 18. 19. 20. 21. 22. 23. 24.

the respiratory chain in the presence of an uncoupler requires the degradation of additional fuel. By oxidizing more fuel (including fat reserves) to produce the same amount of ATP, the body loses weight. When the P/O ratio approaches zero, the lack of ATP results in death. . Valinomycin acts as an uncoupler. It combines with K^+ to form a complex that passes through the inner mitochondrial membrane, dissipating the membrane potential. ATP synthesis decreases, which causes the rate of electron transfer to increase. This results in an increase in the H^+ gradient, O_2 consumption, and amount of heat released. . (a) The formation of ATP is inhibited. (b) The formation of ATP is tightly coupled to electron transfer: 2,4-dinitrophenol is an uncoupler of oxidative phosphorylation. (c) Oligomycin . Cytosolic malate dehydrogenase plays a key role in the transport of reducing equivalents across the inner mitochondrial membrane via the malate-aspartate shuttle. (a) Glycolysis becomes anaerobic. (b) Oxygen consumption ceases. (c) Lactate formation increases. (d) ATP synthesis decreases to 2 ATP/glucose. The steady-state concentration of P_i in the cell is much higher than that of ADP. The P_i released by ATP hydrolysis changes total $[P_i]$ very little. The response to (a) increased $[ADP]$ is faster because the response to (b) reduced pO_2 , requires protein synthesis. (a) NADH is reoxidized via electron transfer instead of lactic acid fermentation. (b) Oxidative phosphorylation is more efficient. (c) The high mass-action ratio of the ATP system inhibits phosphofructokinase-1. Fermentation to ethanol could be accomplished in the presence of O_2 , which is an advantage because strict anaerobic conditions are difficult to maintain. The Pasteur effect is not observed, since the citric acid cycle and electron-transfer chain are inactive. More-efficient electron transfer between complexes. (a) External medium: $4.0 \times 10^{-7} \text{ M}$; matrix: $2.0 \times 10^{-8} \text{ M}$ (b) $[H^+]$ gradient contributes 1.7 kJ/mol toward ATP synthesis (c) 21 (d) No (e) From the overall transmembrane potential (a) $0.91 \text{ W/mol/s} + g$ (b) 5.5 s ; to provide a constant level of ATP, regulation of ATP production must be tight and rapid. $53 \text{ } \mu\text{mol/s} + g$. With a steady state $[ATP]$ of $7.0 \text{ } \mu\text{mol/g}$, this is equivalent to 10 turnovers of the ATP pool per second; the reservoir would last about 0.13 s . Reactive oxygen species react with macromolecules, including DNA. If a mitochondrial defect leads to increased production of ROS, the

nuclear genes that encode proto-oncogenes can be damaged, producing oncogenes and leading to unregulated cell division and cancer (see Section 12.12). Different extents of heteroplasmy for the defective gene produce different degrees of defective mitochondrial function. The inner mitochondrial membrane is impermeable to NADH, but the reducing equivalents of NADH are transferred (shuttled) through the membrane indirectly: they are transferred to oxaloacetate in the cytosol, the resulting malate is transported into the matrix, and mitochondrial NAD⁺ is reduced to NADH. The citric acid cycle is stalled for lack of an acceptor of electrons from NADH. Pyruvate produced by glycolysis cannot enter the cycle as acetyl-CoA; accumulated pyruvate is transaminated to alanine and exported to the liver. Pyruvate dehydrogenase is located in mitochondria, glyceraldehyde 3-phosphate dehydrogenase in the cytosol. The NAD pools are separated by the inner mitochondrial membrane. Complete lack of glucokinase (two defective alleles) makes it impossible to carry out glycolysis at a sufficient rate to raise [ATP] to the threshold required for insulin secretion. 25. 26. 27. 28. 29. 30. 31. 32. 33. 34. 35. 36. 37. 38. 39. 40. 41. 42.

Abbreviated Solutions to Problems AS-23 Defects in Complex II result in increased production of ROS, damage to DNA, and mutations that lead to unregulated cell division (cancer; see Section 12.12). It is not clear why the cancer tends to occur in the midgut. For the maximum photosynthetic rate, PSI (which absorbs light of 700 nm) and PSII (which absorbs light of 680 nm) must be operating simultaneously. The extra weight comes from the water consumed in the overall reaction. Purple sulfur bacteria use HS as the hydrogen donor in photosynthesis. No O₂ is evolved, because the single photosystem lacks the manganese-containing water-splitting complex. 0.44 (a) Stops (b) Slows; some electron flow continues by the cyclic pathway. During illumination, a proton gradient is established. When ADP and P_i are added, ATP synthesis is driven by the gradient, which becomes exhausted in the absence of light. DCMU blocks electron transfer between PSII and the first site of ATP production. In the presence of venturicidin, proton movement through the CF₁CF₀ complex is blocked, and electron flow (oxygen evolution) continues only until the free-energy cost of pumping protons against the rising proton gradient equals the free energy available in a photon. DNP, by dissipating the proton gradient, restores electron flow and oxygen evolution. (a) 56 kJ/

mol (b) 0.29 V From the difference in reduction potentials, one can calculate that $\Delta G'^{\circ} = 15 \text{ kJ/mol}$ for the redox reaction. Fig. 19-48 shows that the energy of photons in any region of the visible spectrum is more than sufficient to drive this endergonic reaction. $1.35 \times 10^{-19} \text{ J}$; the reaction is highly unfavorable! In chloroplasts, the input of light energy overcomes this barrier. —920 kJ/mol No. The electrons from H₂O flow to the artificial electron acceptor Fe^{3+} , not to NADP⁺. About once every 0.1 s; 1 in 10^6 is excited. Light of 700 nm excites PSI but not PSII; electrons flow from P700 to NADP⁺, but no electrons flow from P680 to replace them. When light of 680 nm excites PSII, electrons tend to flow to PSI, but the electron carriers between the two photosystems quickly become completely reduced. No. The excited electron from P700 returns to refill the electron “hole” created by illumination. PSII is not needed to supply electrons, and no O₂ is evolved from H₂O. NADPH is not formed, because the excited electron returns to P700. (a) (1) The presence of Mg^{2+} supports the hypothesis that chlorophyll is directly involved in catalysis of the phosphorylation reaction: $\text{ADP} + \text{P}_i \rightarrow \text{ATP}$. (2) Many enzymes (or other proteins) that contain Mg^{2+} are not phosphorylating enzymes, so the presence of Mg^{2+} in chlorophyll does not prove its role in phosphorylation reactions. (3) The presence of Mg^{2+} is essential to chlorophyll’s photochemical properties: light absorption and electron transfer. (b) (1) Enzymes catalyze reversible reactions, so an isolated enzyme that can, under certain laboratory conditions, catalyze removal of a phosphoryl group could probably, under different conditions (such as in cells), catalyze addition of a phosphoryl group. So it is plausible that chlorophyll could be involved in the phosphorylation of ADP. (2) There are two possible explanations: the chlorophyll protein is a phosphatase only and does not catalyze ADP phosphorylation under cellular conditions, or the crude preparation contains a contaminating phosphatase activity that is unconnected to the photosynthetic reactions. (3) It is likely that the preparation was contaminated with a nonphotosynthetic

AS-24 Abbreviated Solutions to Problems phosphatase activity. (c) (1) This light inhibition is what one would expect if the chlorophyll protein catalyzed the reaction $\text{ADP} + \text{P}_i + \text{light} \rightarrow \text{ATP}$. Without light, the reverse reaction, a dephosphorylation, would be favored. In the presence of light, energy is provided and the equilibrium would shift to the right, reducing the phosphatase activity. (2) This inhibition must be an artifact of the isolation or assay methods. (3) It is unlikely that the crude preparation methods in use at the time preserved intact chloroplast membranes, so the inhibition must be an artifact. (d) (1) In the presence of light, ATP is synthesized and other phosphorylated intermediates are consumed. (2) In the presence of light, glucose is produced and is metabolized by cellular respiration to produce ATP, with changes in the levels of phosphorylated intermediates. (3) In the presence of light, ATP is produced and other phosphorylated intermediates are consumed. (e) Light energy is used to produce ATP (as in the Emerson model) and is used to produce reducing power (as in the Rabinowitch model). (f) The approximate stoichiometry for photophosphorylation (Chapter 19) is that 8 photons yield 2 NADPH and about 3 ATP. Two NADPH and 3 ATP are required to reduce 1 CO₂ (Chapter 20). Thus, at a minimum, 8 photons are required per CO₂ molecule reduced. This is in good agreement with Rabinowitch's value. (g) Because the energy of light is used to produce both ATP and NADPH, each photon absorbed contributes more than just 1 ATP for photosynthesis. The process of energy extraction from light is more efficient than Rabinowitch supposed, and plenty of energy is available for this process—even with red light. Chapter 20 1. Within subcellular organelles, concentrations of specific enzymes and metabolites are elevated; separate pools of cofactors and intermediates are maintained; regulatory mechanisms affect only one set of enzymes and pools. . This observation suggests that ATP and NADPH are generated in the light and are essential for CO₂ fixation; conversion stops as the supply of ATP and NADPH becomes exhausted. Furthermore, some enzymes are switched off in the dark. . X is 8-phosphoglycerate; Y is ribulose 1,5-bisphosphate. . Ribulose 5-phosphate kinase, fructose 1,6-bisphosphatase, sedoheptulose 1,7-bisphosphatase, and glyceraldehyde 3-phosphate dehydrogenase; all are activated by reduction of a critical disulfide bond to a pair of sulfhydryls; iodoacetate reacts irreversibly with

free sulfhydryls. . To carry out the disulfide exchange reaction that activates the Calvin cycle enzymes, thioredoxin needs both of its sulfhydryl groups. . Reductive pentose phosphate pathway regenerates ribulose 1,5-bisphosphate from triose phosphates produced during photosynthesis. Oxidative pentose phosphate pathway provides NADPH for reductive biosynthesis and pentose phosphates for nucleotide synthesis. . Both types of “respiration” occur in plants, consume O_2 , and produce CO_2 . (Mitochondrial respiration also occurs in animals.) Mitochondrial respiration occurs continuously; electrons derived from various fuels are passed through a chain of carriers in the inner mitochondrial membrane to O_2 . Photorespiration occurs in chloroplasts, peroxisomes, and mitochondria. Photorespiration occurs during the daytime, when photosynthetic carbon fixation is occurring; mitochondrial respiration occurs primarily at night, or during cloudy days. The path of electron flow in photorespiration is shown in Fig. 20-21; that for mitochondrial respiration, in Fig. 19-19. . This hypothesis assumes directed evolution, or evolution with a purpose—ideas not generally accepted by evolutionary biologists. Other processes, such as burning fossil fuels and global deforestation, affect the global atmospheric composition. 10. 11. 12. 13. 14. 15. 16. 17. 18. 19. 20. C_4 ; plants, by fixing CO_2 , under conditions when rubisco prefers O_2 ; as substrate, also contributes to setting atmospheric CO_2/O_2 ratios. . (a) Without production of NADPH by the pentose phosphate pathway, cells would be unable to synthesize lipids and other reduced products. (b) Without generation of ribulose 1,5-bisphosphate, the Calvin cycle is effectively blocked. In maize, CO_2 is fixed by the C_4 pathway elucidated by Hatch and Slack, in which PEP is carboxylated rapidly to oxaloacetate (some of which undergoes transamination to aspartate) and reduced to malate. Only after subsequent decarboxylation does the CO_2 enter the Calvin cycle. Measure the rate of fixation of “ C carbon dioxide in the light (daytime) and the dark. Greater fixation in the dark identifies the CAM plant. One could also determine the titratable acidity; acids stored in the vacuole during the night can be quantified in this way. Isocitrate dehydrogenase reaction Storage consumes 1 mol of ATP per mole of glucose 6-phosphate; this represents 3.3% of the total ATP available from glucose 6-phosphate metabolism (i.e., the efficiency of storage is 96.7%). [PP_i] is high in the cytosol because the cytosol lacks inorganic pyrophosphatase. (a) Low [P_j] in the

cytosol and high [triose phosphate] in the chloroplast (b) High [triose phosphate] in the cytosol 3-Phosphoglycerate is the primary product of photosynthesis; [P_i] rises when light-driven synthesis of ATP from ADP and P_i slows. (a) Sucrose + (glucose), > (glucose),,,,; + fructose (b) Fructose generated in the synthesis of dextran is readily imported and metabolized by the bacteria. Species 1 is Cy; species 2, Cs. (a) In peripheral chloroplasts (b), (c) In central sphere (a) By analogy to the oxygenic photosynthesis carried out by plants (H₂O + CO₂ → glucose + O₂), the reaction would be HS + O₂ + CO₂ → glucose + H₂O + S. This is the sum of the reduction of CO₂ by HS (HS + CO₂ → glucose + S) and the energy input (HS + O₂ → S + H₂O). (b) The HS and CO₂ are produced chemically in deep-sea sediments, but the O₂, like the vast majority of O₂ on Earth, is produced by photosynthesis, which is driven by light energy. (c) In the assay used by Robinson et al., ³H labels the C-1 of ribulose 1,5-bisphosphate, so reaction with CO₂ yields one molecule of [³H]3-phosphoglycerate and one molecule of unlabeled 3-phosphoglycerate; reaction with O₂ produces one molecule of (³H)2-phosphoglycolate and one molecule of unlabeled 3-phosphoglycerate. Thus the ratio of [³H]3-phosphoglycerate to (³H)2-phosphoglycolate equals the ratio of carboxylation to oxygenation. (d) If the ³H labeled C-5, both oxygenation and carboxylation would yield [³H]3-phosphoglycerate and it would be impossible to distinguish which reaction had produced the labeled product; the reaction could not be used to measure Q. $\frac{[\text{CO}_2]}{[\text{O}_2]} = \frac{0.00038}{0.2} = 0.0019$ (e) Substituting = 0.0019 into $\frac{\text{Rate of carboxylation}}{\text{Rate of oxygenation}} = Q$ gives $Q = \frac{0.0019}{0.016} = 0.119$ (0.0019) = 0.016 Voxygenation Therefore, the rate of oxygenation would be roughly 60 times the rate of carboxylation! (f) If terrestrial plants had Q = 8.6, carboxylation would occur at a much lower rate than oxygenation. This would be extremely inefficient, so one would expect the rubisco of terrestrial plants to have an Q substantially higher than 8.6. In fact, Q values for land plants vary between 10 and 250. Even with these values, the expected rate of the oxygenation reaction is still very high. (g) The rubisco reaction occurs with CO₂ as a gas. At the same

temperature, CO, molecules diffuse more slowly than the lighter CO, molecules, and thus ^{13}CO , will enter the active site (and become incorporated into substrate) more slowly than ^{12}CO ; (h) For the relationship to be truly symbiotic, the tube worms must be getting a substantial amount of their carbon from the bacteria. The presence of rubisco in the endosymbionts simply shows that they are capable of chemosynthesis, not that they are supplying the host with a significant fraction of its carbon. On the other hand, showing that the $^{13}\text{C}:^{12}\text{C}$ ratio in the host is more similar to that in the endosymbiont than that in other marine animals strongly suggests that the tube worms are getting the majority of their carbon from the bacteria.

Chapter 21 1. 10. 11. . 3 Palmitate + glycerol + 7ATP

4 (a) The 16 carbons of palmitate are derived from 8 acetyl groups of 8 acetyl-CoA molecules. The C-labeled acetyl-CoA gives rise to malonyl-CoA labeled at C-1 and C-2. (b) The metabolic pool of malonyl-CoA, the source of all palmitate carbons except C-16 and C-15, does not become labeled with small amounts of C-labeled acetyl-CoA. Hence, only $[15,16\text{-}^{13}\text{C}]$ palmitate is formed. . Both glucose and fructose are degraded to pyruvate in glycolysis. Pyruvate is converted to acetyl-CoA by the pyruvate dehydrogenase complex. Some of this acetyl-CoA enters the citric acid cycle, which produces reducing equivalents (NADH and NADPH). Mitochondrial electron transfer to O_2 yields ATP. . 8 Acetyl-CoA + 15ATP + 14NADPH + 9H₂O > palmitate + 8CoA + 15ADP + 15P, + 14NADP* + 2H* . (a) 3 deuteriums per palmitate; all located on C-16; all other two-carbon units are derived from unlabeled malonyl-CoA. (b) 7 deuteriums per palmitate; located on all even-numbered carbons except C-16. . By using the three-carbon unit malonyl-CoA, the activated form of acetyl-CoA (recall that malonyl-CoA synthesis requires ATP), metabolism is driven in the direction of fatty acid synthesis by the exergonic release of CO₂. . The rate-limiting step in fatty acid synthesis is carboxylation of acetyl-CoA, catalyzed by acetyl-CoA carboxylase. High [citrate] and [isocitrate] indicate that conditions are favorable for fatty acid synthesis: an active citric acid cycle is providing a plentiful supply of ATP, reduced pyridine nucleotides, and acetyl-CoA. Citrate stimulates (increases the V_{max} of) acetylCoA carboxylase (a). Because citrate binds more tightly to the filamentous form of the enzyme (the active form), high [citrate] drives the protomer = = filament

equilibrium in the direction of the active form (b). In contrast, palmitoyl-CoA (the end product of fatty acid synthesis) drives the equilibrium in the direction of the inactive (protomer) form. Hence, when the end product of fatty acid synthesis accumulates, the biosynthetic path slows. . (a) Acetyl-CoA + ATP + CoA → acetyl-CoA + ADP + P_i + CoA (b) 1 ATP per acetyl group (c) Yes . The double bond in palmitoleate is introduced by an oxidation catalyzed by fatty acyl-CoA desaturase, a mixed-function oxidase that requires O₂ as a cosubstrate. 4H₂O → tripalmitin + 7ADP + 7P_i + 7H⁺ In adult rats, stored triacylglycerols are maintained at a steady-state level through a balance of the rates of degradation and biosynthesis. Hence, the triacylglycerols of adipose (fat) tissue are constantly turned over, which explains the incorporation of ¹⁴C label from dietary glucose. Net reaction: Dihydroxyacetone phosphate + NADH + palmitate + oleate + 3ATP + CTP + choline + 4H₂O → phosphatidylcholine + NAD⁺ + 2AMP + ADP + H⁺ + CMP + 5P_i; 1 ATP per molecule of phosphatidylcholine 12. 13. 14. 15. 16. 17. 18. 19. Abbreviated Solutions to Problems AS-25 Methionine deficiency reduces the level of adoMet, which is required for the de novo synthesis of phosphatidylcholine. The salvage pathway does not employ adoMet, but uses available choline. Thus phosphatidylcholine can be synthesized even when the diet is deficient in methionine, as long as choline is available. ¹⁴C label appears in three places in the activated isoprene: “CH₂ C—“CH₂—CH₂— M₄CH₂, (a) ATP (b) UDP-glucose (c) CDP-ethanolamine (d) UDPgalactose (e) fatty acyl-CoA (f) S-adenosylmethionine (g) malonyl-CoA (h) A'-isopentenyl pyrophosphate Linoleate is required in the synthesis of prostaglandins. Animals are unable to transform oleate to linoleate, so linoleate is an essential fatty acid. Plants can transform oleate to linoleate, and they provide animals with the required linoleate (see Fig. 21-12). The rate-determining step in the biosynthesis of cholesterol is the synthesis of mevalonate, catalyzed by hydroxymethylglutaryl-CoA reductase. This enzyme is allosterically regulated by mevalonate and cholesterol derivatives. High intracellular [cholesterol] also reduces transcription of the gene encoding HMG-CoA reductase. When cholesterol levels decline because of treatment with a statin, cells attempt to compensate by increasing expression of the gene encoding HMG-CoA reductase. The statins are good competitive inhibitors of HMG-CoA reductase

activity nonetheless and reduce overall production of cholesterol. Note: There are several plausible alternatives that a student might propose in the absence of a detailed knowledge of the literature on this enzyme. Thiolase reaction: Begins with nucleophilic attack of an active-site Cys residue on the first acetyl-CoA substrate, displacing —S-CoA and forming a covalent thioester link between Cys and the acetyl group. A base on the enzyme then extracts a proton from the methyl group of the second acetyl-CoA, leaving a carbanion that attacks the carbonyl carbon of the thioester formed in the first step. The sulfhydryl of the Cys residue is displaced, creating the product acetoacetyl-CoA. HMG-CoA synthase reaction: Begins in the same way, with a covalent thioester link formed between the enzyme's Cys residue and the acetyl group of acetyl-CoA, with displacement of the —S-CoA . The —S-CoA dissociates as CoA-SH , and acetoacetyl-CoA binds to the enzyme. A proton is abstracted from the methyl group of the enzyme-linked acetyl, forming a carbanion that attacks the ketone carbonyl of the acetoacetyl-CoA substrate. The carbonyl is converted to a hydroxyl ion in this reaction, and this is protonated to create —OH . The thioester link with the enzyme is then cleaved hydrolytically to generate the HMG-CoA product. HMG-CoA reductase reaction: Two successive hydride ions derived from NADPH first displace the —S-CoA , and then reduce the aldehyde to a hydroxyl group. Statins inhibit HMG-CoA reductase, an enzyme in the pathway to the synthesis of activated isoprenes, which are precursors of cholesterol and a wide range of isoprenoids, including coenzyme Q (ubiquinone). Hence, statins might reduce the levels of coenzyme available for mitochondrial respiration. Ubiquinone is obtained in the diet as well as by direct biosynthesis, but it is not yet clear how much is required and how well dietary sources can substitute for reduced synthesis. Reductions in the levels of particular isoprenoids may account for some side effects of statins.

AS-26 Abbreviated Solutions to Problems 20. (a)

Astaxanthin phosphate and formation of a double bond between the B and y carbons. A rearrangement (beginning with proton abstraction at the pyridoxal carbon adjacent to the substrate amino nitrogen) moves the double bond between the a and B carbons, and converts the ketimine to the aldimine form of PLP. Attack of water at the B carbon is then facilitated by the linked pyridoxal, followed by hydrolysis of the imine link between PLP and the product, to generate threonine. 4. In the mammalian route, toxic ammonium ions are transformed (b) Head-to-head. There are two ways to look at this. First, the to glutamine, reducing toxic effects on the brain. "tail" of geranylgeranyl pyrophosphate has a branched dimethyl 5. Glucose + 2CO₂ + 2NH₃ → 2 aspartate + 2H⁺ + 2H₂O structure, as do both ends of phytoene. Second, no free —OH 6. The amino-terminal glutaminase domain is quite similar in all is formed by the release of PP_i, indicating that the two glutamine amidotransferases. A drug that targeted this active —O—(P)— "heads" are linked to form phytoene. (e) Four site would probably inhibit many enzymes and thus be prone rounds of dehydrogenation convert four single bonds to double to producing many more side effects than a more specific bonds. (d) No. A count of single and double bonds in the inhibitor targeting the unique carboxyl-terminal synthetase reaction below shows that one double bond is replaced by two active site. single bonds—so, there is no net oxidation or reduction: 7. If phenylalanine hydroxylase is defective, the biosynthetic route to tyrosine is blocked and tyrosine must be obtained ~ < a from the diet. D > SA A o S` 8. In adoMet synthesis, triphosphate is released from ATP. Lycopene (C-40) Hydrolysis of the triphosphate renders the reaction a thermodynamically more favorable. | pena ends around foricyèlization 9. If the inhibition of glutamine synthase were not concerted, saturating concentrations of histidine would shut down the enzyme and cut off production of glutamine, which the bacterium needs to synthesize other products. 10. Folic acid is a precursor of tetrahydrofolate (see Fig. 18-16), required in the biosynthesis of glycine (see Fig. 22-14), a precursor of porphyrins. A folic acid deficiency therefore impairs hemoglobin synthesis. 11. For glycine auxotrophs: adenine and guanine; for glutamine auxotrophs: adenine, guanine, and cytosine; for aspartate B-Carotene (C-40) auxotrophs: adenine, guanine, cytosine, and

uridine. 12. (a) See Fig. 18-6, step ©, for the reaction mechanism of amino Ce) Steps @ through ©. The enzyme can convert IPP and acid racemization. The F atom of fluoroalanine is an excellent DMAP to geranylgeranyl pyrophosphate, but catalyzes no further leaving group. Fluoroalanine causes irreversible (covalent) reactions in the pathway, as confirmed by results with the other inhibition of alanine racemase. One plausible mechanism is (Nuc substrates. (f) Strains 1 through 4 lack crt# and have much denotes any nucleophilic amino acid side chain in the enzyme lower astaxanthin production than strains 5 through 8, all of active site): which overexpress crt. Thus, overexpression of crtE leads to a substantial increase in astaxanthin production. Wild-type *Æ. coli* yms B—EnD CEDA has some step © activity, but this conversion of farnesyl i HB Nuc H Nus pyrophosphate to geranylgeranyl pyrophosphate is strongly rate- -00C -C cH LF -00C —C Sé m, -00C—C—CH, limiting. (g) IPP isomerase. Comparing strains 5 and 6 shows that Al F Ht | adding ispA, which catalyzes steps @ and @, has little effect on | J | | astaxanthin production, so these steps are not rate-limiting. CH CH CH However, comparing strains 5 and 7 shows that adding idi HO HO HO substantially increases astaxanthin production, so IPP isomerase N | N | N must be the rate-limiting step when crtE is overexpressed. (h) A tf tf + f low (+) level, comparable to that of strains 5, 6, and 9. Without CH; N CH; N CH; N overexpression of çdi, production of astaxanthin is limited by low IPP isomerase activity and the resulting limited supply of IPP. Chapter 22 1. In their symbiotic relationship with the plant, bacteria supply ammonium ion by reducing atmospheric nitrogen, which requires large quantities of ATP. . The transfer of nitrogen from NH₃ to carbon skeletons can be catalyzed by (1) glutamine synthetase and (2) glutamate dehydrogenase. The latter enzyme produces glutamate, the amino group donor in all transamination reactions, necessary to the formation of amino acids for protein synthesis. . A link between enzyme-bound PLP and the phosphohomoserine substrate is first formed, with rearrangement to generate the ketimine at the a carbon of the substrate. This activates the B carbon for proton abstraction, leading to displacement of the 13. 14. (b) Azaserine (see Fig. 22-51) is an analog of glutamine. The diazoacetyl group is highly reactive and forms covalent bonds with nucleophiles at the active site of a glutamine amidotransferase. (a) As shown in Fig. 18-16, p-aminobenzoate is a component of N^o,N^o-

methylenetetrahydrofolate, the cofactor involved in the transfer of one-carbon units. (b) In the presence of sulfanilamide, a structural analog of p-aminobenzoate, bacteria are unable to synthesize tetrahydrofolate, a cofactor necessary for converting AICAR to FAICAR; thus AICAR accumulates. (c) The competitive inhibition by sulfanilamide of the enzyme involved in tetrahydrofolate biosynthesis is overcome by the addition of excess substrate (p-aminobenzoate). The ¹⁴C-labeled orotate arises from the following pathway (the first three steps are part of the citric acid cycle):

$\text{-00C} \text{---} \text{"CH}_2\text{---"CH}_2\text{---} \text{"COO Succinate} \mid \text{-00}^* \text{C H} \text{"C= uc Z}$

Abbreviated Solutions to Problems AS-27 Organisms do not store nucleotides to be used as fuel, and they do not completely degrade them, but rather hydrolyze them to release the bases, which can be recovered in salvage pathways. The low C:N ratio of nucleotides makes them poor sources of energy. Treatment with allopurinol has two consequences. (1) It inhibits conversion of hypoxanthine to uric acid, causing accumulation of hypoxanthine, which is more soluble and more readily excreted; this alleviates the clinical problems associated with AMP degradation. (2) It inhibits conversion of guanine to uric acid, causing accumulation of xanthine, which is less soluble than uric acid; this is the source of xanthine stones. Because the amount of GMP degradation is low relative to AMP degradation, the kidney damage caused by xanthine stones is less than that caused by untreated gout. 5-Phosphoribosyl-1-pyrophosphate; this is the first NH acceptor in the purine biosynthetic pathway. (a) The α -carboxyl group is removed and an ---OH is added to the γ carbon. (b) BtrI has sequence homology with acyl carrier proteins. The molecular weight of BtrI increases when incubated under conditions in which CoA could be added to the protein. Adding CoA to a Ser residue would replace an ---OH (formula weight (FW) 17) with a 4'-phosphopantetheine group (see Fig. 21-5). This group has the formula $\text{C}_{11}\text{H}_{18}\text{N}_2\text{O}_7\text{P}_2\text{S}$ (FW 356). Thus, $11,182 \text{---} 17 + 356 = 12,151$, which is very close to the observed M, of 12,153. (c) The thioester could form with the α -carboxyl group. (d) In the most common reaction for removing the α -carboxyl group of an amino acid (see Fig. 18-6c), the carboxyl group must be free. Furthermore, it is difficult to imagine a decarboxylation reaction starting with a carboxyl group in its thioester form. (e) $12,240 \text{---} 12,281 = 41$, close to the M, of CO₂ (44). Given that BtrK is probably a decarboxylase, its most likely structure is the decarboxylated form: Hy S BtrI C₁₂ 12,370 $\text{---} 12,240 = 130$. Glutamic acid (C₅H₉NO₄; M, 147), minus the ---OH (FW 17) removed in the glutamylation reaction, leaves a glutamyl group of FW 130; thus, γ -glutamylating the molecule

above would add 130 to its M_r. BtrJ is capable of γ-glutamylating
 other substrates, so it may γ-glutamylate the structure above. The
 most likely site for this is the free amino group, giving the following
 structure: O O = AAA O O γ nory *NH; S \$ BtrI (g) + + NH; NH;
 CO, on 0 Bird on 10 BtrK O QO ATP ADP O S + BtrI BtrI Glutamate
 HN“ ~

Os Antibiotic Chapter 23 1 10. 11. . They are recognized by two different receptors, typically found in different cell types, and are coupled to different downstream effects. . Steady-state levels of ATP are maintained by phosphoryl group transfer to ADP from phosphocreatine. 1-Fluoro-2,4-dinitrobenzene inhibits creatine kinase. . Ammonia is very toxic to nervous tissue, especially the brain. Excess NH_4^+ is removed by transformation of glutamate to glutamine, which travels to the liver and is subsequently transformed to urea. The additional glutamine arises from the transformation of glucose to α -ketoglutarate, transamination of α -ketoglutarate to glutamate, and conversion of glutamate to glutamine. . Glucogenic amino acids are used to make glucose for the brain; others are oxidized in mitochondria via the citric acid cycle. . From glucose, by the following route: Glucose — dihydroxyacetone phosphate (in glycolysis); dihydroxyacetone phosphate + $\text{NADH} + \text{H}^+ \rightarrow$ glycerol 3-phosphate + NAD^+ (glycerol 3-phosphate dehydrogenase reaction) . (a) Increased muscular activity increases the demand for ATP, which is met by increased O_2 consumption. (b) After the sprint, lactate produced by anaerobic glycolysis is converted to glucose and glycogen, which requires ATP and therefore O_2 . . Glucose is the primary fuel of the brain. TPP-dependent oxidative decarboxylation of pyruvate to acetyl-CoA is essential to complete glucose metabolism. = 190 m . (a) Inactivation provides a rapid means to change hormone concentrations. (b) Insulin level is maintained by equal rates of synthesis and degradation. (c) Changes in the rate of release from storage, rate of transport, and rate of conversion from prohormone to active hormone. Water-soluble hormones bind to receptors on the outer surface of the cell, triggering the formation of a second messenger (e.g., cAMP) inside the cell. Lipid-soluble hormones can pass through the plasma membrane to act on target molecules or receptors directly. (a) Heart and skeletal muscle lack glucose 6-phosphatase. Any glucose 6-phosphate produced enters the glycolytic pathway, and under O_2 -deficient conditions is converted to lactate via pyruvate. (b) In a “fight or flight” situation, the concentration of glycolytic precursors must be high in preparation

for muscular 12. 13. 14. 15. 16. 17. 18. 19. 20. 21. 22. activity. Phosphorylated intermediates cannot escape from the cell, because the membrane is not permeable to charged species, and glucose 6-phosphate is not exported on the glucose transporter. The liver, by contrast, must release the glucose necessary to maintain blood glucose level; glucose is formed from glucose 6-phosphate and enters the bloodstream. (a) Excessive uptake and use of blood glucose by the liver, leading to hypoglycemia; shutdown of amino acid and fatty acid catabolism (b) Little circulating fuel is available for ATP requirements. Brain damage results because glucose is the main source of fuel for the brain. Thyroxine acts as an uncoupler of oxidative phosphorylation. Uncouplers lower the P/O ratio, and the tissue must increase respiration to meet the normal ATP demands. Thermogenesis could also be due to the increased rate of ATP utilization by the thyroid-stimulated tissue, as increased ATP demands are met by increased oxidative phosphorylation and thus respiration. Because prohormones are inactive, they can be stored in quantity in secretory granules. Rapid activation is achieved by enzymatic cleavage in response to an appropriate signal. In animals, glucose can be synthesized from many precursors (see Fig. 14-16). In humans, the principal precursors are glycerol from triacylglycerols and glucogenic amino acids from protein. The ob/ob mouse, which is initially obese, will lose weight. The OB/OB mouse will retain its normal body weight. BMI = 39.3. For BMI of 25, weight must be 75 kg; must lose 43 kg = 95 lbs. Reduced insulin secretion. Valinomycin has the same effect as opening the K^+ channel, allowing K^+ exit and consequent hyperpolarization. The liver does not receive the insulin message and therefore continues to have high levels of glucose 6-phosphatase and gluconeogenesis, increasing blood glucose both during a fast and after a glucose-containing meal. The elevated blood glucose triggers insulin release from pancreatic B cells, hence the high level of insulin in the blood. Some things to consider: What is the frequency of heart attack attributable to the drug? How does this frequency compare with the number of individuals spared the long-term consequences of type 2 diabetes? Are other, equally effective treatment options with fewer adverse effects available? Without intestinal glucosidase activity, absorption of glucose from dietary glycogen and starch is reduced, blunting the usual rise in blood glucose after the meal. The undigested oligosaccharides are fermented by bacteria in the large

intestine, and the gases released cause intestinal discomfort. (a) Closing the ATP-gated K^+ channel would depolarize the membrane, leading to increased insulin release. (b) Type 2 diabetes results from decreased sensitivity to insulin, not a deficit of insulin production; increasing circulating insulin levels will reduce the symptoms associated with this disease. (c) Individuals with type 1 diabetes have deficient pancreatic B cells, so glyburide will have no beneficial effect. (d) Iodine, like chlorine (the atom it replaces in the labeled glyburide), is a halogen, but it is a larger atom and has slightly different chemical properties. It is possible that the iodinated glyburide would not bind to SUR. If it bound to another molecule instead, the experiment would result in cloning of the gene for this other, incorrect protein. (e) Although a protein has been “purified,” the “purified” preparation might be a mixture of several proteins that co-purify under those experimental conditions. In this case, the amino acid sequence could be that of a protein that co-purifies with SUR. Using antibody binding to show that the peptide sequences are present in SUR excludes this possibility. (f) Although the cloned gene does encode the 25 amino acid sequence found in SUR, it could be a gene that, coincidentally, encodes the same sequence in another protein. In this case, this

other gene would most likely be expressed in different cells than the SUR gene. The mRNA hybridization results are consistent with the putative SUR cDNA actually encoding SUR. (g) The excess unlabeled glyburide competes with labeled glyburide for the binding site on SUR. As a result, there is significantly less binding of labeled glyburide, so little or no radioactivity is detected in the 140 kDa protein. (h) In the absence of excess unlabeled glyburide, labeled 140 kDa protein is found only in the presence of the putative SUR cDNA. Excess unlabeled glyburide competes with the labeled glyburide, and no I-labeled 140 kDa protein is detected. This shows that the cDNA produces a glyburide-binding protein of the same molecular weight as SUR— strong evidence that the cloned gene encodes the SUR protein. (i) Several additional steps are possible, such as: (1) Express the putative SUR cDNA in CHO (Chinese hamster ovary) cells and show that the transformed cells have ATP-gated K^+ channel activity. (2) Show that HIT cells with mutations in the putative SUR gene lack ATP-gated K^+ channel activity. (3) Show that experimental animals or human patients with mutations in the putative SUR gene are unable to secrete insulin.

Chapter 24 1. 2. 10. 11. 6.1×10^8 nm; 290 times longer than the T2 phage head The number of A residues does not equal the number of T residues, nor does the number of G equal the number of C, so the DNA is not a base-paired double helix; the M13 DNA is single-stranded. . $M_r = 3.8 \times 10^6$; length = 200 μ m; $L_k = 55,200$; $L_k = 51,900$. The exons contain 3 bp/amino acid $\times 192$ amino acids = 576 bp. The remaining 864 bp are in introns, possibly in a leader or signal sequence, and/or in other noncoding DNA. . 5,000 bp. (a) Doesn't change; L_k cannot change without breaking and re-forming the covalent backbone of the DNA. (b) Becomes undefined; a circular DNA with a break in one strand has, by definition, no L_k . (c) Decreases; in the presence of ATP, gyrase underwinds DNA. (d) Doesn't change; this assumes that neither of the DNA strands is broken in the heating process. . For L_k to remain unchanged, the topoisomerase must introduce the same number of positive and negative supercoils. . $\sigma = -0.067$; >70% probability . (a) Undefined; the strands of a nicked DNA could be separated and thus have no L_k . (b) 476 (c) 476; the DNA is already relaxed, so the topoisomerase does not cause a net change. (d) 460; gyrase plus ATP reduces the L_k in increments of 2. (e) 464; eukaryotic type I

topoisomerases increase the Lk of underwound or negatively supercoiled DNA in increments of 1. (£) 460; nucleosome binding does not break any DNA strands and thus cannot change Lk. . A fundamental structural unit in chromatin repeats about every 200 bp; the DNA is accessible to the nuclease only at 200 bp intervals. The brief treatment was insufficient to cleave the DNA at every accessible point, so a ladder of DNA bands is created in which the DNA fragments are multiples of 200 bp. The thickness of the DNA bands suggests that the distance between cleavage sites varies somewhat. For instance, not all the fragments in the lowest band are exactly 200 bp long. A right-handed helix has a positive Lk; a left-handed helix (such as Z-DNA) has a negative Lk. Decreasing the Lk of a closed circular B-DNA by underwinding it facilitates formation of regions of Z-DNA within certain sequences. (See Chapter 8, p. 291, for a description of sequences that permit the formation of Z-DNA.) (a) Both strands must be covalently closed, and the molecule must be either circular or constrained at both ends. (b) Formation of cruciforms, left-handed Z-DNA, plectonemic or solenoidal supercoils, and unwinding of the DNA are favored. (c) *Æ. coli* DNA topoisomerase II or DNA gyrase. (d) It binds the DNA at a point where it crosses on itself, cleaves both strands of one of the crossing segments, passes the other segment through the break, then reseals the break. The result is a change in Lk of -2 . 12. 13. 14. 15. 16. 17. Abbreviated Solutions to Problems AS-29

Centromere, telomeres, and an autonomous replicating sequence or replication origin The bacterial nucleoid is organized into domains approximately 10,000 bp long. Cleavage by a restriction enzyme relaxes the DNA within a domain, but not outside the domain. Any gene in the cleaved domain for which expression is affected by DNA topology will be affected by the cleavage; genes outside the domain will not. (a) The lower, faster-migrating band is negatively supercoiled plasmid DNA. The upper band is nicked, relaxed DNA. (b) DNA topoisomerase I relaxes the supercoiled DNA. The lower band will disappear, and all of the DNA will converge on the upper band. (ce) DNA ligase produces little change in the pattern. Some minor additional bands may appear near the upper band, due to the trapping of topoisomers not quite perfectly relaxed by the ligation reaction. (d) The upper band will disappear, and all of the DNA will be in the lower band. The supercoiled DNA in the lower band may become even more supercoiled and migrate somewhat faster. (a)

When DNA ends are sealed to create a relaxed, closed circle, some DNA species are completely relaxed but others are trapped in slightly under- or overwound states. This gives rise to a distribution of topoisomers centered on the most relaxed species. (b) Positively supercoiled. (c) The DNA that is relaxed despite the addition of dye is DNA with one or both strands broken. DNA isolation procedures inevitably introduce small numbers of strand breaks in some of the closed-circular molecules. (d) Approximately -0.05 . This is determined by simply comparing native DNA with samples of known α . In both gels, the native DNA migrates most closely with the sample of $\alpha = -0.049$. 62 million (the genome refers to the haploid genetic content of the cell; the cell is actually diploid, so the number of nucleosomes is doubled). The number comes from 3.1 billion base pairs divided by 200 base pairs per nucleosome (giving 15.5 million nucleosomes), multiplied by two copies of H2A per nucleosome and again multiplied by 2 to account for the diploid state of the cell. The 62 million would double upon replication. (a) In nondisjunction, one daughter cell and all of its descendants get two copies of the synthetic chromosome and are white; the other daughter cell and all of its descendants get no copies of the synthetic chromosome and are red. This gives rise to a half-white, half-red colony. (b) In chromosome loss, one daughter cell and all of its descendants get one copy of the synthetic chromosome and are pink; the other daughter and all its descendants get no copies of the synthetic chromosome and are red. This gives rise to a half-pink, half-red colony. (c) The minimum functional centromere must be smaller than 0.63 kbp, since all fragments of this size or larger confer relative mitotic stability. (d) Telomeres are required to fully replicate only linear DNA; a circular molecule can replicate without them. (e) The larger the chromosome, the more faithfully it is segregated. The data show neither a minimum size below which the synthetic chromosome is completely unstable, nor a maximum size above which stability no longer changes. (69) 102 10 H z 1

AS-30 Abbreviated Solutions to Problems stable. This suggests that other, as yet undiscovered, elements 3'-triphosphate, displacing pyrophosphate. Note that this are required for stability. mechanism would require the evolution of new metabolic pathways to supply the needed deoxynucleotide 3'-triphosphates. Chapter 25 [z] 5' end Z 1. In random, dispersive replication, in the second generation, all HO—CH, the DNAs would have the same density and would appear as a single band, not the two bands observed in the Meselson-Stahl experiment. 2. In this extension of the Meselson-Stahl experiment, after three generations the molar ratio of 'N—'4N DNA to MN—"N DNA is $2/6 = 0.33$. 3. (a) 4.42×10^6 turns; (b) 40 min. In cells dividing every 20 min, a replicative cycle is initiated every 20 min, each cycle beginning before the prior one is complete. (e) 2,000 to 5,000 Okazaki fragments. The fragments are 1,000 to 2,000 nucleotides long and are firmly bound to the template strand by base pairing. Each fragment is quickly joined to the lagging strand, thus preserving the correct order of the fragments. 4, A 28.7%; G 21.3%; C 21.3%; T 28.7%. The DNA strand made from the template strand: A 32.7%; G 18.5%; C 24.1%; T 24.7%; the DNA strand made from the complementary template strand: A 24.7%; G 24.1%; C 18.5%; T 32.7%. It is assumed that the two template strands are replicated completely. 5. (a) No. Incorporation of ^{32}P into DNA results from the synthesis of new DNA, which requires the presence of all | four nucleotide precursors. (b) Yes. Although all four $\sim\text{O}-\text{P}=\text{O} \sim\text{O}-\text{P}=\text{O}$ nucleotide precursors must be present for DNA synthesis, i b only one of them has to be radioactive in order for radioactivity to appear in the new DNA. (c) No. Radioactivity is incorporated only if the ^{32}P label is in the a phosphate; 7 DNA polymerase cleaves off pyrophosphate—i.e., the B- and y-phosphate groups. 3' end : 3' end: . The DNA polymerase contains a 3'—>5' exonuclease activity that degrades DNA to produce [^{32}P]dNMPs. The activity is not a 5' 3' exonuclease, because the addition of unlabeled dNTPs 6. Mechanism 1: 3'-OH of an incoming dNTP attacks the a inhibits the production of [^{32}P]dNMPs (polymerization activity phosphate of the triphosphate at the 5' end of the growing DNA would suppress a proofreading exonuclease but not an strand, displacing pyrophosphate. This mechanism uses normal exonuclease operating downstream of the polymerase). Addition dNTPs, and the growing

end of the DNA always has a of pyrophosphate would generate [^{32}P]dNTPs through reversal triphosphate on the 5' end. of the polymerase reaction. 5' end Z 8. Leading strand: Precursors: dATP, dGTP, dCTP, dTTP (also needs a template DNA strand and DNA primer); enzymes and other proteins: DNA gyrase, helicase, single-stranded DNA-binding protein, DNA polymerase III, topoisomerases, and pyrophosphatase. Lagging strand: Precursors: ATP, GTP, CTP, UTP, dATP, dGTP, dCTP, dTTP (also needs an RNA primer); enzymes and other proteins: DNA gyrase, helicase, single-stranded DNA-binding protein, primase, DNA polymerase III, DNA polymerase I, DNA ligase, topoisomerases, and pyrophosphatase. NAD⁺ is also required as a cofactor for DNA ligase. 9. Mutants with defective DNA ligase produce a DNA duplex in which one of the strands remains in pieces (as Okazaki fragments). When this duplex is denatured, sedimentation results in one fraction containing the intact single strand (the high molecular weight band) and one fraction containing the unspliced fragments (the low molecular weight band). 10. Watson-Crick base pairing between template and leading strand; proofreading and removal of wrongly inserted nucleotides by the 3'-exonuclease activity of DNA polymerase III. Yes—perhaps. Because the factors ensuring fidelity of replication are operative in both the leading and the lagging strands, the lagging strand would probably be made with the same fidelity. However, the greater number of distinct chemical operations involved in $\sim\text{O}-\text{P}=\text{O}$ making the lagging strand might provide a greater opportunity, 3' end: for errors to arise. 3' end : 11. $\sim 1,200$ bp (600 in each direction) Mechanism 2: This uses a new type of precursor, nucleotide 3'- 12. A small fraction (13 of 10^6 cells) of the histidine-requiring triphosphates. The growing end of the DNA strand has a 5'-OH, mutants spontaneously undergo back-mutation and regain their which attacks the a phosphate of an incoming deoxynucleotide capacity to synthesize histidine. 2-Aminoanthracene increases

13. 14. 15. 16. 17. 18. the rate of back-mutations about 1,800-fold and is therefore mutagenic. Since most carcinogens are mutagenic, 2-aminoanthracene is probably carcinogenic. Spontaneous deamination of 5-methylcytosine (see Fig. 8-30) produces thymine, and thus a G-T mismatched pair. These are among the most common mismatches in the DNA of eukaryotes. The specialized repair system restores the G = C pair. (a) Ultraviolet irradiation produces pyrimidine dimers; in normal fibroblasts these are excised by cleavage of the damaged strand by a special excinuclease. Thus the denatured singlestranded DNA contains the many fragments caused by the cleavage, and the average molecular weight is lowered. These fragments of single-stranded DNA are absent from the XPG samples, as indicated by the unchanged average molecular weight. (b) The absence of fragments in the single-stranded DNA from the XPG cells after irradiation suggests the special excinuclease is defective or missing. During homologous genetic recombination, a Holliday intermediate may be formed almost anywhere within the two paired, homologous chromosomes; the branch point of the intermediate can move extensively by branch migration. In sitespecific recombination, the Holliday intermediate is formed between two specific sites, and branch migration is generally restricted by heterologous sequences on either side of the recombination sites. (a) Points Y. (b) Points X. Once replication has proceeded from the origin to a point where one recombination site has been replicated but the other has not, site-specific recombination not only inverts the DNA between the recombination sites but also changes the direction of one replication fork relative to the other. The forks will chase each other around the DNA circle, generating many tandem copies of the plasmid. The multimeric circle can be resolved to monomers by additional site-specific recombination events. Origin Origin initiation of recombination at replication sites 1 and 2 (inversion) 2 2 Plasmid with Partially recombination replicated sites 1 and 2 plasmid Origin continued Origin unidirectional replication Plasmid with reoriented replication forks Multimeric plasmid (a) Even in the absence of an added mutagen, background mutations occur due to radiation, cellular chemical reactions, and so forth. (b) If the DNA is sufficiently damaged, a substantial fraction of gene products are nonfunctional and the cell is nonviable. (c) Cells with reduced DNA

repair capability are more sensitive to mutagens. Because they less readily repair lesions caused by R7000, *uvr⁻* bacteria have an increased mutation rate and increased chance of lethal effects. (d) In the *uvr⁺* strain, the excision-repair system removes DNA bases with attached [³H]R7000, decreasing the ³H in these cells over time. Abbreviated Solutions to Problems AS-31 In the *uvr⁻* strain, the DNA is not repaired and the ³H level increases as [³H]R7000 continues to react with the DNA. (e) All mutations listed in the table except A = T to G = C show significant increases over background. Each type of mutation results from a different type of interaction between R7000 and DNA. Because different types of interactions are not equally likely (due to differences in reactivity, steric constraints, etc.), the resulting mutations occur with different frequencies. (f) No. Only those that start with a G = C base pair are explained by this model. Thus A = T to C = G and A = T to T = A must be due to R7000 attaching to an A or a T. (g) R7000-G pairs with A. First, R7000 adds to G = C to give R7000-G = C. (Compare this with what happens with the CH₃-G in Fig. 25-27b.) If this is not repaired, one strand is replicated as R7000-G = A, which is repaired to T = A. The other strand is wild-type. If the replication produces R7000-G = T, a similar pathway leads to an A = T base pair. (h) No. Compare data in the two tables, and keep in mind that different mutations occur at different frequencies. A = T to C = G: moderate in both strains; but better repair in the *uvr⁺* strain G = C to A = T: moderate in both; no real difference G = C to C = G: higher in *uvr⁺*; certainly less repair! G = C to T = A: high in both; no real difference A = T to T = A: high in both; no real difference A = T to G = C: low in both; no real difference Certain adducts may be more readily recognized by the repair apparatus than others and thus are repaired more rapidly and result in fewer mutations. Chapter 26 1. 2 (a) 60 to 100 s; (b) 500 to 900 nucleotides . A single base error in DNA replication, if not corrected, would cause one of the two daughter cells, and all its progeny, to have a mutated chromosome. A single base error in RNA transcription would not affect the chromosome; it would lead to formation of some defective copies of one protein, but because mRNAs turn over rapidly, most copies of the protein would not be defective. The progeny of this cell would be normal. . Normal posttranscriptional processing at the 3' end (cleavage and polyadenylation) would be inhibited or blocked. . Because the template-strand RNA does not encode the enzymes

needed to initiate viral infection, it would probably be inert or simply degraded by cellular ribonucleases. Replication of the template-strand RNA and propagation of the virus could occur only if intact RNA replicase (RNA-dependent RNA polymerase) were introduced into the cell along with the template strand. .

AUGACCAUGAUUACG . (1) Use of a template strand of nucleic acid; (2) synthesis in the 5'—3' direction; (3) use of nucleoside triphosphate substrates, with formation of a phosphodiester bond and displacement of PP. Polynucleotide phosphorylase forms phosphodiester bonds but differs in all other listed properties. .

Generally two: one to cleave the phosphodiester bond at one intron-exon junction, the other to link the resulting free exon end to the exon at the other end of the intron. If the nucleophile in the first step were water, this step would be a hydrolytic event and only one transesterification step would be required to complete the splicing process. . Many snoRNAs, required for rRNA modification reactions, are encoded in introns. If splicing does not occur, snoRNAs are not produced. . These enzymes lack a 3'—> 5' proofreading exonuclease and have a high error rate; the likelihood of a replication error that would inactivate the virus is much less in a small genome than in a large one.

AS-32 Abbreviated Solutions to Problems 10. (a) $4'' = 1.8 \times 10!''$ (b) 0.006% (c) For the “unnatural selection” 11. 12. step, use a chromatographic resin with a bound molecule that is a transition-state analog of the ester hydrolysis reaction. Though RNA synthesis is quickly halted by α -amanitin toxin, it takes several days for the critical mRNAs and the proteins in the liver to degrade, causing liver dysfunction and death. (a) After lysis of the cells and partial purification of the contents, the protein extract could be subjected to isoelectric focusing. The B subunit could be detected by an antibody-based assay. The difference in amino acid residues between the normal B subunit and the mutated form (i.e., the different charges on the amino acids) would alter the electrophoretic mobility of the mutant protein in an isoelectric focusing gel, relative to the protein from a nonresistant strain. (b) Direct DNA sequencing (by the Sanger method). 13. 14. (a) 384 nucleotide pairs (b) 1,620 nucleotide pairs (e) Most of the nucleotides are untranslated regions at the 3' and 5' ends of the mRNA. Also, most mRNAs code for a signal sequence (Chapter 27) in their protein products, which is eventually cleaved off to produce the mature and functional protein. (a) cDNA is produced by reverse transcription of mRNA; thus, the mRNA sequence is probably CGG. Because the genomic DNA transcribed to make the mRNA has the sequence CAG, the primary transcript most likely has CAG, which is posttranscriptionally modified to CGG. (b) The unedited mRNA sequence is the same as that of the DNA (except for U replacing T). Unedited mRNA has the sequence (* indicates site of editing) k (5')

ACGGAAATACGCCGTTTCCTACGCTATAAAGCGGTTTC(5') This gives

the 22 nucleotide product. (c) Treatments (proteases, heat) known to disrupt protein function inhibit the editing activity, whereas treatments (nuclease) that do not affect proteins have little or no effect on editing. A key weakness of this argument is that the protein-disrupting treatments do not completely abolish editing. There could be some background editing or degradation of the mRNA even without the enzyme, or some of the enzyme might survive the treatments. (d) Only the α phosphate of NTPs is incorporated into polynucleotides. If the researchers had used the other types of [^{32} P]NTPs, none of the products would have been labeled. (e) Because only an A is being edited, only the fate of any A in the sequence is of interest. (f) Given that only ATP was labeled, if the entire nucleotide were removed, all radioactivity would have been removed from the mRNA, so only unmodified [^{32} P]AMP would be present on the chromatography plate. (g) If the base were removed and replaced, one would expect to see only [7H]AMP. The presence of [PH]IMP indicates that the A to I change occurs without removal of H at positions 2 and 8. The most likely mechanism

is chemical modification of A to I by hydrolytic deamination (see Fig. 22-36). Ch) CAG is changed to CIG. This codon is read as CGG. Chapter 27 1. (a) Gly—Gln—Ser—Leu—Leu-Ile (b) Leu—Asp—Ala—Pro (Ce) His—Asp—Ala—Cys—Cys—Tyr (d) Met—Asp—Glu in eukaryotes; fMet—Asp—Glu in bacteria . UUAAUGUAU, UUGAUGUAU, CUUAUGUAU, CUCAUGUAU, CUA AUGUAU, CUGAUGUAU, UUA AUGUAC, UUGAUGUAC, CUUAUGUAC, CUCAUGUAC, CUA AUGUAC, CUGAUGUAC . No. Because nearly all the amino acids have more than one codon (e.g., Leu has six), any given polypeptide can be coded for by a number of different base sequences. However, some amino acids are encoded by only one codon and those with multiple codons often share the same nucleotide at two of the three positions, so certain parts of the mRNA sequence encoding a protein of known amino acid sequence can be predicted with high certainty. . (a) (5')CGACGGCGCGAAGUCAGGGGUGUUAAG(3') (b) Arg—Arg—Arg—Glu-Val—Arg—Gly—Val-Lys (ce) No. The complementary antiparallel strands in doublehelical DNA do not have the same base sequence in the 5' > 3' direction. RNA is transcribed from only one specific strand of duplex DNA. The RNA polymerase must therefore recognize and bind to the correct strand. . There are two tRNAs for methionine: tRNATM, which is the initiating tRNA, and tRNA[“], which can insert a Met residue in interior positions in a polypeptide. Only fMet-tRNA^{TM*} is recognized by the initiation factor IF-2 and is aligned with the initiating AUG positioned at the ribosomal P site in the initiation complex. AUG codons in the interior of the mRNA can bind and incorporate only Met-tRNATM. . Allow polynucleotide phosphorylase to act on a mixture of UDP and CDP in which UDP has, say, five times the concentration of CDP. The result would be a synthetic RNA polymer with many UUU triplets (coding for Phe), a smaller number of UUC (Phe), UCU (Ser), and CUU (Leu), a much smaller number of UCC (Ser), CUC (Leu), and CCU (Pro), and the smallest number of CCC (Pro). . A minimum of 583 ATP equivalents (based on 4 per amino acid residue added, except that there are only 145 translocation steps). Correction of each error requires 2 ATP equivalents. For glycogen synthesis, 292 ATP equivalents. The extra energy cost for B-globin synthesis reflects the cost of the information content of the protein. At least 20 activating enzymes, 70 ribosomal proteins, 4 rRNAs, 32

or more tRNAs, an mRNA, and 10 or more auxiliary enzymes must be made by the eukaryotic cell in order to synthesize a protein from amino acids. The synthesis of an (n > 4) chain of glycogen from glucose requires only 4 or 5 enzymes (Chapter 15). Glycine codons Anticodons (5')GGU (5')ACC, GCC, ICC (5')GGC (5')GCC, ICC (5')GGA (5')UCC, ICC (5')GGG (5')CCC, UCC (a) The 3' and middle position (b) Pairings with anticodons (5')GCC, ICC, and UCC (e) Pairings with anticodons (5')ACC and CCC . (a), (c), (e), and (g) only; (b), (d), and (f) cannot be the result of single-base mutations: (b) and (f) would require substitutions of two bases, and (d) would require substitutions of all three bases. 10. 11. 12. 13. 14. 15. 16.

17. 18. 19. Abbreviated Solutions to Problems AS-33

(5')AUGAUAUUGCUAUCUUGGACU Changes: CC AUU C C U C A A G G G 14 of 63 possible one-base changes would result in no coding change. The two DNA codons for Glu are GAA and GAG, and the four DNA codons for Val are GTT, GTC, GTA, and GTG. A single base change in GAA to form GTA or in GAG to form GTG could account for the Glu — Val replacement in sickle-cell hemoglobin. Much less likely are two-base changes, from GAA to GTG, GTT, or GTC; and from GAG to GTA, GTT, or GTC. Isoleucine is similar in structure to several other amino acids, particularly valine.

Distinguishing between valine and isoleucine in the aminoacylation process requires the second filter of a proofreading function.

Histidine has a structure unlike that of any other amino acid, and this structure provides opportunities for binding specificity adequate to ensure accurate aminoacylation of the cognate tRNA.

(a) The Ala-tRNA synthetase recognizes the G⁺-U⁺ base pair in the amino acid arm of tRNA^{Ala}. (b) The mutant tRNA^{Ala} would insert Ala residues at codons encoding Pro. (c) A mutation that might have similar effects is an alteration in tRNA^{Ala} that allowed it to be recognized and aminoacylated by Ala-tRNA synthetase. (d) Most of the proteins in the cell would be inactivated, so these would be lethal mutations and hence never observed. This represents a powerful selective pressure for maintaining the genetic code. IF-2: The 70S ribosome would form, but initiation factors would not be released and elongation could not start. EF-Tu: The second aminoacyl-tRNA would bind to the ribosomal A site, but no peptide bond would form. EF-G: The first peptide bond would form, but the ribosome would not move along the mRNA to vacate the A site for binding of a new EF-Tu-tRNA. The amino acid most recently added

to a growing polypeptide chain is the only one covalently attached to a tRNA and thus is the only link between the polypeptide and the mRNA encoding it. A proofreading activity would sever this link, halting synthesis of the polypeptide and releasing it from the mRNA. The protein would be directed into the ER, and from there the targeting would depend on additional signals. SRP binds the amino-terminal signal early in protein synthesis and directs the nascent polypeptide and ribosome to receptors in the ER. Because the protein is translocated into the lumen of the ER as it is synthesized, the NLS is never accessible to the proteins involved in nuclear targeting. Trigger factor is a molecular chaperone that stabilizes an unfolded and translocation-competent conformation of ProOmpA. DNA with a minimum of 5,784 bp; some of the coding sequences must be nested or overlapping. (a) The helices associate through hydrophobic and van der Waals interactions. (b) R groups 3, 6, 7, and 10 extend to the left; 1, 2, 4, 5, 8, and 9 extend to the right. (c) One possible sequence is 1 2 3 4 5 6 7 8 9 10 N—Phe—Ile—Glu—Val—Met—Asn—Ser—Ala—Phe—Gln—C (d) One possible DNA sequence for the amino acid sequence in (c) is Nontemplate strand (5' TTTATTGAAGTAATGAATAGTGCATTCC AG(3') PETE P TEEPE EPP P PP bit rb tbirtte (8 AAATAACTTCATTACTTATCACGTAAGGTC(5') Template strand

AS-34 Abbreviated Solutions to Problems (e) Phe, Leu, Ile, Met, and Val. All are hydrophobic, but the set does not include all the hydrophobic amino acids; Trp, Pro, Ala, and Gly are missing. (f) Tyr, His, Gln, Asn, Lys, Asp, and Glu. All of these are hydrophilic, although Tyr is less hydrophilic than the others. The set does not include all the hydrophilic amino acids; Ser, Thr, and Arg are missing. (g) Omitting T from the mixture excludes codons starting or ending with T—thus excluding Tyr, which is not very hydrophilic, and, more importantly, excluding the two possible stop codons (TAA and TAG). No other amino acids in the NAN set are excluded by omitting T. (h) Misfolded proteins are often degraded in the cell. Therefore, if a synthetic gene has produced a protein that forms a band on the SDS gel, it is likely that this protein is folded properly. (i) Protein folding depends on more than hydrophobic and van der Waals interactions. There are many reasons why a synthesized random sequence protein might not fold into the four-helix structure. For example, hydrogen bonds between hydrophilic side chains could disrupt the structure. Also, not all sequences have an equal propensity to form an α helix. Chapter 28

1. 10. (a) Tryptophan synthase levels remain high in spite of the presence of tryptophan. (b) Levels again remain high. (c) Levels rapidly decrease, preventing wasteful synthesis of tryptophan. . The *E. coli* cells will produce β -galactosidase when they are subjected to high levels of a DNA-damaging agent, such as UV light. Under such conditions, RecA binds to single-stranded chromosomal DNA and facilitates the autocatalytic cleavage of the LexA repressor, releasing LexA from its binding site and allowing transcription of downstream genes. . (a) Constitutive, low-level expression of the operon; most mutations in the operator would make the repressor less likely to bind. (b) Either constitutive expression, as in (a), or constant repression, if the mutation destroyed the capability to bind to lactose and related compounds and hence the response to inducers. (c) Either increased or decreased expression of the operon (under conditions in which it is induced), depending on whether the mutation made the promoter more or less similar, respectively, to the consensus *E. coli* promoter. . $7,000$ copies . 8×10^{-9} M, about 10^6 times greater than the dissociation constant. With 10^6 copies of active repressor in the cell, the operator site is always bound by the repressor molecule. . (a)-(c) Each condition decreases expression of

lac operon genes. . (a) Less attenuation of transcription. The ribosome completing the translation of sequence 1 would no longer overlap and block sequence 2; sequence 2 would always be available to pair with sequence 3, preventing formation of the attenuator structure. (b) More attenuation of transcription. Sequence 2 would pair less efficiently with sequence 3; the attenuator structure would be formed more often, even when sequence 2 was not blocked by a ribosome. (c) No attenuation of transcription. The only regulation would be that afforded by the Trp repressor. (d) Attenuation loses its sensitivity to Trp tRNA. It might become sensitive to His tRNA. (e) Attenuation would rarely, if ever, occur. Sequences 2 and 3 always block formation of the attenuator. (f) Constant attenuation of transcription. Attenuator always forms, regardless of the availability of tryptophan. . Induction of the SOS response could not occur, making the cells more sensitive to high levels of DNA damage. . Each Salmonella cell would have flagella made up of both types of flagellar protein, and the cell would be vulnerable to antibodies generated in response to either protein. A dissociable factor necessary for activity (e.g., a specificity factor similar to the σ subunit of the *E. coli* enzyme) may have been lost during purification of the polymerase.

11. Gal4 protein Gal4 DNA-binding domain Gal4 activator domain Engineered protein Lac repressor DNA-binding domain Gal4 activator domain

12. 13. 14. The engineered protein cannot bind to the Gal4 binding site in the GAL gene (UASq) because it lacks the Gal4 DNA-binding domain. Modify the Gal4p DNA binding site to give it the nucleotide sequence to which the Lac repressor normally binds (using methods described in Chapter 9).

Methylamine. The reaction proceeds with attack of water on the guanidinium carbon of the modified arginine. The bcd mRNA needed for development is contributed to the egg by the mother. The egg develops normally even if its genotype is *bcd* / *bcd*_, as long as the mother has one normal *bcd* gene and the *bcd* allele is recessive. However, the adult *bcd* / *bcd* female will be sterile because she has no normal *bcd* mRNA to contribute to her own eggs.

(a) For 10% expression (90% repression), 10% of the repressor has bound inducer and 90% is free and available to bind the operator. The calculation uses Eqn 5-8 (p. 161), with $6 = 0.1$ and $K_y = 10^7$.

$$[IPTG] [IPTG] [IPTG] + K_a [IPTG] + 10^7 m [IPTG] = r = \frac{50}{0.9} [IPTG] = 10'' \text{ or } [IPTG] = 1.1 \times 10^6 m [IPTG] + 10^7 m$$

For 90% expression, 90% of the repressor

has bound inducer, so $\theta = 0.9$. Entering the values for θ and K_4 in Eqn 5-8 gives $[IPTG] = 9 \times 10^{-6} M$. Thus, gene expression varies 10-fold over a roughly 10-fold $[IPTG]$ range. (b) You would expect the protein levels to be low before induction, rise during induction, and then decay as synthesis stops and the proteins are degraded. (c) As shown in (a), the lac operon has more levels of expression than just on or off; thus it does not have characteristic A. As shown in (b), expression of the lac operon subsides once the inducer is removed; thus it lacks characteristic B. (d) GFP-on: rep^{TM} and GFP are expressed at high levels; rep' represses OP,, so no LacI protein is produced. GFP-off: Lac] is expressed at a high level; LacI represses OP,,, so rep'' and GFP are not produced. (e) IPTG treatment switches the system from GFP-off to GFP-on. IPTG has an effect only when LacI is present, so affects only the GFP-off state. Adding IPTG relieves the repression of OPy,., allowing high-level expression of rep' , which turns off expression of LacI, and high-level expression of GFP. (f) Heat treatment switches the system from GFP-on to GFP-off. Heat has an effect only when rep'' is present, so affects only the GFP-on state. Heat inactivates rep'' and relieves the repression of OP,, allowing highlevel expression of LacI. LacI then acts at OP), to repress synthesis of rep and GFP. (g) Characteristic A: The system is not stable in the intermediate state. At some point, one repressor will act more strongly than the other due to chance fluctuations in expression; this shuts off expression of the other repressor and locks the system in one state. Characteristic B: Once one repressor is expressed, it prevents the synthesis of the other; thus the system remains in one state even after the switching stimulus has been removed. (h) At no time does any cell express an intermediate level of GFP—this is a confirmation of characteristic A. At the intermediate concentration (X) of inducer, some cells have switched to GFP-on while others have not yet made the switch and remain in the GFP-off state; none are in between. The bimodal distribution of expression levels at $[IPTG] = X$ is caused by the mixed population of GFP-on and GFP-off cells.

Glossary ABC transporters: Plasma membrane proteins with sequences that make up ATP-binding cassettes; serve to transport a large variety of substrates, including inorganic ions, lipids, and nonpolar drugs, out of the cell, using ATP as the energy source. absolute configuration: The configuration of four different substituent groups around an asymmetric carbon atom, in relation to D- and L-glyceraldehyde. absorption: Transport of the products of digestion from the intestinal tract into the blood. acceptor control: Regulation of the rate of respiration by the availability of ADP as phosphate group acceptor. accessory pigments: Visible light—absorbing pigments (carotenoids, xanthophylls, and phycobilins) in plants and photosynthetic bacteria that complement chlorophylls in trapping energy from sunlight. acid dissociation constant: The dissociation constant (K_a) of an acid, describing its dissociation into its conjugate base and a proton. acidosis: A metabolic condition in which the capacity of the body to buffer H^+ is diminished; usually accompanied by decreased blood pH. actin: A protein that makes up the thin filaments of muscle; also an important component of the cytoskeleton of many eukaryotic cells. action spectrum: A plot of the efficiency of light at promoting a light-dependent process such as photosynthesis as a function of wavelength. activation energy ($\Delta G^\ddagger$): The amount of energy (in joules) required to convert all the molecules in 1 mol of a reacting substance from the ground state to the transition state. activator: (1) A DNA-binding protein that positively regulates the expression of one or more genes; that is, transcription rates increase when an activator is bound to the DNA. (2) A positive modulator of an allosteric enzyme. active site: The region of an enzyme surface that binds the substrate molecule and catalytically transforms it; also known as the catalytic site. active transport: Energy-requiring transport of a solute across a membrane in the direction of increasing concentration. activity: The true thermodynamic activity or potential of a substance, as distinct from its molar concentration. acyl phosphate: Any molecule with the general chemical form $FaaA$ adaptor proteins: Signaling proteins, generally without their own enzymatic activities, that have binding sites for two or more cellular components and serve to bring those components together. adenosine 3',5'-cyclic monophosphate: See cyclic AMP. S-adenosylmethionine (adoMet): An enzymatic cofactor involved in methyl group transfers. adipocyte: An animal cell

specialized for the storage of fats (triacylglycerols). adipose tissue: Connective tissue specialized for the storage of large amounts of triacylglycerols. See also brown adipose tissue; white adipose tissue. ADP (adenosine diphosphate): A ribonucleoside 5'-diphosphate serving as phosphate group acceptor in the cell energy cycle. aerobic: An organism that lives in air and uses oxygen as the terminal electron acceptor in respiration. aerobic: Requiring or occurring in the presence of oxygen. agonist: A compound, typically a hormone or neurotransmitter, that elicits a physiological response when it binds to its specific receptor. alcohol fermentation: See ethanol fermentation. aldose: A simple sugar in which the carbonyl carbon atom is an aldehyde; that is, the carbonyl carbon is at one end of the carbon chain. alkalosis: A metabolic condition in which the capacity of the body to buffer OH is diminished; usually accompanied by an increase in blood pH. allosteric enzyme: A regulatory enzyme with catalytic activity modulated by the noncovalent binding of a specific metabolite at a site other than the active site. allosteric protein: A protein (generally with multiple subunits) with multiple ligand-binding sites, such that ligand binding at one site affects ligand binding at another. allosteric site: The specific site on the surface of an allosteric enzyme molecule to which the modulator or effector molecule is bound. α helix: A helical conformation of a polypeptide chain, usually right-handed, with maximal intrachain hydrogen bonding; one of the most common secondary structures in proteins. α oxidation: An alternative path for the oxidation of β -methyl fatty acids in peroxisomes. Ames test: A simple bacterial test for carcinogenicity, based on the assumption that carcinogens are mutagens. amino acid activation: ATP-dependent enzymatic esterification of the carboxyl group of an amino acid to the 3'-hydroxyl group of its corresponding tRNA. amino acids: α -Amino-substituted carboxylic acids, the building blocks of proteins. aminoacyl-tRNA: An aminoacyl ester of a tRNA. aminoacyl-tRNA synthetases: Enzymes that catalyze synthesis of an aminoacyl-tRNA at the expense of ATP energy. amino-terminal residue: The only amino acid residue in a polypeptide chain with a free α -amino group; defines the amino terminus of the polypeptide. aminotransferases: Enzymes that catalyze the transfer of amino groups from α -amino to α -keto acids; also called transaminases. ammonotelic: Excreting excess nitrogen in the form of ammonia. AMP-activated protein kinase (AMPK): A

protein kinase activated by 5'-adenosine monophosphate (AMP). AMPK action generally shifts metabolism away from biosynthesis toward energy production. amphibolic pathway: A metabolic pathway used in both catabolism and anabolism. amphipathic: Containing both polar and nonpolar domains. amphitropic proteins: Proteins that associate reversibly with the membrane and thus can be found in the cytosol, in the membrane, or in both places. ampholyte: A substance that can act as either a base or an acid. amphoteric: Capable of donating and accepting protons, thus able to serve as an acid or a base. AMPK: See AMP-activated protein kinase. amyloidoses: A variety of progressive conditions characterized by abnormal deposits of misfolded proteins in one or more organs or tissues. anabolism: The phase of intermediary metabolism concerned with the energy-requiring biosynthesis of cell components from smaller precursors. anaerobe: An organism that lives without oxygen. Obligate anaerobes die when exposed to oxygen. anaerobic: Occurring in the absence of air or oxygen. analyte: A molecule to be analyzed by mass spectrometry. anammox: Anaerobic oxidation of ammonia to N_2 , using nitrite as electron acceptor; carried out by specialized chemolithotrophic bacteria. anaplerotic reaction: An enzyme-catalyzed reaction that can replenish the supply of intermediates in the citric acid cycle. angstrom (Å): A unit of length (10^{-10} m) used to indicate molecular dimensions. G-1

G-2 Glossary anhydride: The product of the condensation of two carboxyl or phosphate groups in which the elements of water are eliminated to form a compound with the general structure $\text{X}-\text{O}-\text{X}$ where X is either carbon or phosphorus. anion-exchange resin: A polymeric resin with fixed cationic groups, used in the chromatographic separation of anions. anomeric carbon: The carbon atom in a sugar at the new stereocenter formed when a sugar cyclizes to form a hemiacetal. This is the carbonyl carbon of aldehydes and ketones. anomers: Two stereoisomers of a given sugar that differ only in the configuration about the carbonyl (anomeric) carbon atom. antagonist: A compound that interferes with the physiological action of another substance (the agonist), usually at a hormone or neurotransmitter receptor. antibiotic: One of many different organic compounds that are formed and secreted by various species of microorganisms and plants, are toxic to other species, and presumably have a defensive function. antibody: A defense protein synthesized by the immune system of vertebrates. See also immunoglobulin. anticodon: A specific sequence of three nucleotides in a tRNA, complementary to a codon for an amino acid in an mRNA. antigen: A molecule capable of eliciting the synthesis of a specific antibody in vertebrates. antiparallel: Describes two linear polymers that are opposite in polarity or orientation. antiport: Cotransport of two solutes across a membrane in opposite directions. apoenzyme: The protein portion of an enzyme, exclusive of any organic or inorganic cofactors or prosthetic groups that might be required for catalytic activity. apolipoprotein: The protein component of a lipoprotein. apoprotein: The protein portion of a protein, exclusive of any organic or inorganic cofactors or prosthetic groups that might be required for activity. apoptosis: (app'-a-toe'-sis) Programmed cell death in which a cell brings about its own death and lysis, in response to a signal from outside or programmed in its genes, by systematically degrading its own macromolecules. aptamer: Oligonucleotide that binds specifically to one molecular target, usually selected by an iterative cycle of affinity-based enrichment (SELEX). aquaporin (AQP): A member of a family of integral membrane proteins that mediate the flow of water across membranes. Archaea: One of the five kingdoms of living organisms; includes many species that thrive in extreme environments of high ionic strength, high temperature, or low pH.

asymmetric carbon atom: A carbon atom that is covalently bonded to four different groups and thus may exist in two different tetrahedral configurations. ATP (adenosine triphosphate): A ribonucleoside 5'-triphosphate functioning as a phosphate group donor in the cellular energy cycle; carries chemical energy between metabolic pathways by serving as a shared intermediate coupling endergonic and exergonic reactions. ATPase: An enzyme that hydrolyzes ATP to yield ADP and phosphate, usually coupled to a process requiring energy. ATP synthase: An enzyme complex that forms ATP from ADP and phosphate during oxidative phosphorylation in the inner mitochondrial membrane or the bacterial plasma membrane, and during photophosphorylation in chloroplasts. attenuator: An RNA sequence involved in regulating the expression of certain genes; functions as a transcription terminator. autophagy: Catabolic lysosomal degradation of cellular proteins and other components. autophosphorylation: Strictly, the phosphorylation of an amino acid residue in a protein that is catalyzed by the same protein molecule; often extended to include phosphorylation of one subunit of a homodimer by the other subunit. autotroph: An organism that can synthesize its own complex molecules from very simple carbon and nitrogen sources, such as carbon dioxide and ammonia. auxin: A plant growth hormone. auxotrophic mutant (auxotroph): A mutant organism defective in the synthesis of a particular biomolecule, which must therefore be supplied for the organism's growth. Avogadro's number (N): The number of molecules in a gram molecular weight (a mole) of any compound (6.02×10^{23}). b Bacteria: One of the five kingdoms of living organisms; bacteria have a plasma membrane but no internal organelles or nucleus. bacteriophage: A virus capable of replicating in a bacterial cell; also called phage. baculovirus: Any of a group of double-stranded DNA viruses that infect invertebrates, particularly insects, and are widely used for purposes of protein expression in biotechnology. basal metabolic rate: An animal's rate of oxygen consumption when at complete rest, long after a meal. base pair: Two nucleotides in nucleic acid chains that are paired by hydrogen bonding of their bases; for example, A with T or U, and G with C. BAT: See brown adipose tissue. B cell: See B lymphocyte. B conformation: An extended, zigzag arrangement of a polypeptide chain; a common secondary structure in proteins. B oxidation: Oxidative degradation of fatty

acids into acetyl-CoA by successive oxidations at the B-carbon atom; as distinct from ω oxidation. **B turn:** A type of protein secondary structure consisting of four amino acid residues arranged in a tight turn so that the polypeptide turns back on itself. **bilayer:** A double layer of oriented amphipathic lipid molecules, forming the basic structure of biological membranes. The hydrocarbon tails face inward to form a continuous nonpolar phase. **bile acids:** Polar derivatives of cholesterol, secreted by the liver into the intestine, that serve to emulsify dietary fats, facilitating lipase action on them. **bile salts:** Amphipathic steroid derivatives with detergent properties, participating in digestion and absorption of lipids. **binding energy:** The energy derived from noncovalent interactions between enzyme and substrate or receptor and ligand. **binding site:** The crevice or pocket on a protein in which a ligand binds. **bioassay:** A method for measuring the amount of a biologically active substance (such as a hormone) in a sample by quantifying the biological response to aliquots of that sample. **bioinformatics:** The computerized analysis of biological data, using methods derived from statistics, linguistics, mathematics, chemistry, biochemistry, and physics. The data are often nucleic acid or protein sequence or structural data, but can also involve experimental data from many sources, patient statistics, and materials in the scientific literature. **Bioinformatics research** focuses on methods for data storage, retrieval, and analysis. **biosphere:** All the living matter on or in the earth, the seas, and the atmosphere. **biotin:** A vitamin; an enzymatic cofactor involved in carboxylation reactions. **B lymphocyte (B cell):** One of a class of blood cells (lymphocytes), responsible for the production of circulating antibodies. **bond energy:** The energy required to break a bond. **branch migration:** Movement of the branch point in a branched DNA formed from two DNA molecules with identical sequences. See also Holliday intermediate. **brown adipose tissue (BAT):** Thermogenic adipose tissue rich in mitochondria that contain the uncoupling protein thermogenin, which uncouples electron transfer through the respiratory chain from ATP synthesis. Compare white adipose tissue. **buffer:** A system capable of resisting changes in pH, consisting of a conjugate acid-base pair in which the ratio of proton acceptor to proton donor is near unity. **c calorie:** The amount of heat required to raise the temperature of 1.0 g of water from 14.5 to 15.5°C. One calorie (cal) equals 4.18 joules (J).

Calvin cycle: The cyclic pathway in plants that fixes carbon dioxide and produces triose phosphates. CAM plants: Succulent plants of hot, dry climates, in which CO₂ is fixed into oxaloacetate in the dark, then fixed by rubisco in the light when stomata close to exclude O₂. cAMP: See cyclic AMP. cAMP receptor protein (CRP): In bacteria, a specific regulatory protein that controls initiation of transcription of the genes that produce the enzymes required for the cell to use some other nutrient when glucose is lacking; also called catabolite gene activator protein (CAP). CAP: See cAMP receptor protein. capsid: The protein coat of a virion or virus particle. carbanion: A negatively charged carbon atom. carbocation: A positively charged carbon atom; also called a carbonium ion. carbohydrate: A polyhydroxy aldehyde or ketone, or substance that yields such a compound on hydrolysis. Many carbohydrates have the empirical formula (CH₂O)_n; some also contain nitrogen, phosphorus, or sulfur. carbon-assimilation reactions: Reaction sequence in which atmospheric CO₂ is converted into organic compounds. carbon-fixation reactions: The reactions, catalyzed by rubisco during photosynthesis or by other carboxylases, in which atmospheric CO₂ is initially incorporated (fixed) into an organic compound. carbonium ion: See carbocation. carboxyl-terminal residue: The only amino acid residue in a polypeptide chain with a free α-carboxyl group; defines the carboxyl terminus of the polypeptide. cardiolipin: A membrane phospholipid in which two phosphatidic acid moieties share a single glycerol head group. carnitine shuttle: Mechanism for moving fatty acids from the cytosol to the mitochondrial matrix as fatty esters of carnitine. carotenoids: Lipid-soluble photosynthetic pigments made up of isoprene units. cascade: See enzyme cascade. catabolism: The phase of intermediary metabolism concerned with the energy-yielding degradation of nutrient molecules. catabolite gene activator protein (CAP): See cAMP receptor protein. catalytic site: See active site. catecholamines: Hormones, such as epinephrine, that are amino derivatives of catechol. catenane: Two or more circular polymeric molecules interlinked by one or more noncovalent topological links, resembling the links of a chain. cation-exchange resin: An insoluble polymer with fixed negative charges, used in the chromatographic separation of cationic substances. cDNA: See complementary DNA. cDNA library: A collection of cloned DNA fragments derived

entirely from the complement of mRNA being expressed in a particular organism or cell type under a defined set of conditions.

cellular differentiation: The process in which a precursor cell becomes specialized to carry out a particular function, by acquiring a new complement of proteins and RNA.

central dogma: The organizing principle of molecular biology: genetic information flows from DNA to RNA to protein.

centromere: A specialized site in a chromosome, serving as the attachment point for the mitotic or meiotic spindle.

cerebroside: Sphingolipid containing one sugar residue as a head group.

channeling: The direct transfer of a reaction product (common intermediate) from the active site of an enzyme to the active site of the enzyme catalyzing the next step in a pathway.

chaperone: Any of several classes of proteins or protein complexes that catalyze the accurate folding of proteins in all cells.

chaperonin: One of two major classes of chaperones found in virtually all organisms; a complex of proteins that functions in protein folding, either GroES/GroEL in bacteria or Hsp60 in eukaryotes.

chemiosmotic coupling: Coupling of ATP synthesis to electron transfer via a transmembrane difference in charge and pH.

chemiosmotic theory: The theory that energy derived from electron transfer reactions is temporarily stored as a transmembrane difference in charge and pH, which subsequently drives the formation of ATP in oxidative phosphorylation and photophosphorylation.

chemotaxis: A cell's sensing of and movement toward or away from a specific chemical agent.

chemotroph: An organism that obtains energy by metabolizing organic compounds derived from other organisms.

chiral center: An atom with substituents arranged so that the molecule is not superposable on its mirror image.

chiral compound: A compound that contains an asymmetric center (chiral atom or chiral center) and thus can occur in two nonsuperposable mirror-image forms (enantiomers).

chlorophylls: A family of green pigments that function as receptors of light energy in photosynthesis; magnesium-porphyrin complexes.

chloroplast: Chlorophyll-containing photosynthetic organelle in some eukaryotic cells.

chondroitin sulfate: One of a family of sulfated glycosaminoglycans, a major component of the extracellular matrix.

chromatin: A filamentous complex of DNA, histones, and other proteins, constituting the eukaryotic chromosome.

chromatography: A process in which complex mixtures of molecules are separated by many repeated

partitionings between a flowing (mobile) phase and a stationary phase. G-3 Glossary chromatophore: A compound or moiety (natural or synthetic) that absorbs visible or ultraviolet light. chromosome: A single large DNA molecule and its associated proteins, containing many genes; stores and transmits genetic information. chylomicron: A plasma lipoprotein consisting of a large droplet of triacylglycerols stabilized by a coat of protein and phospholipid; carries lipids from the intestine to the tissues. circular dichroism spectroscopy: A method used to characterize the degree of folding in a protein, based on differences in the absorption of right-handed versus left-handed circularly polarized light. cis and trans isomers: See geometric isomers. cistron: A unit of DNA or RNA corresponding to one gene. citric acid cycle: A cyclic pathway for the oxidation of acetyl residues to carbon dioxide, in which formation of citrate is the first step; also known as the Krebs cycle or tricarboxylic acid cycle. clones: The descendants of a single cell. cloning: The production of large numbers of identical DNA molecules, cells, or organisms from a single ancestral DNA molecule, cell, or organism. closed system: A system that exchanges neither matter nor energy with the surroundings. See also system. cobalamin: See coenzyme B₁₂. coding strand: In DNA transcription, the DNA strand identical in base sequence to the RNA transcribed from it, with U in the RNA in place of T in the DNA; as distinct from the template strand. Also called the nontemplate strand. codon: A sequence of three adjacent nucleotides in a nucleic acid that codes for a specific amino acid. coenzyme: An organic cofactor required for the action of certain enzymes; often has a vitamin component. coenzyme A: A pantothenic acid-containing coenzyme that serves as an acyl group carrier in certain enzymatic reactions. coenzyme B₁₂: An enzymatic cofactor derived from the vitamin cobalamin, involved in certain types of carbon skeletal rearrangements. cofactor: An inorganic ion or a coenzyme required for enzyme activity. cognate: Describes two biomolecules that normally interact; for example, an enzyme and its usual substrate, or a receptor and its usual ligand. cohesive ends: See sticky ends. cointegrate: An intermediate in the migration of certain DNA transposons in which the donor DNA and target DNA are covalently attached. colligative properties: Properties of a solution that depend on the number of solute particles per unit volume; for example, freezingpoint depression. combinatorial control: Use of

combinations of a limited repertoire of regulatory proteins

G-4 Glossary to provide gene-specific regulation of many individual genes.

competitive inhibition: A type of enzyme inhibition reversed by increasing the substrate concentration; a competitive inhibitor generally competes with the normal substrate or ligand for a protein's binding site.

complementary: Having a molecular surface with chemical groups arranged to interact specifically with chemical groups on another molecule.

complementary DNA (cDNA): A DNA complementary to a specific mRNA, used in DNA cloning; usually made by reverse transcriptase.

condensation: A reaction type in which two compounds are joined with the elimination of water.

configuration: The spatial arrangement of an organic molecule that is conferred by the presence of either (1) double bonds, about which there is no freedom of rotation, or (2) chiral centers, around which substituent groups are arranged in a specific sequence. Configurational isomers cannot be interconverted without breaking one or more covalent bonds.

conformation: A spatial arrangement of substituent groups that are free to assume different positions in space, without breaking any bonds, because of the freedom of bond rotation.

conjugate acid-base pair: A proton donor and its corresponding deprotonated species; for example, acetic acid (donor) and acetate (acceptor).

conjugated protein: A protein containing one or more prosthetic groups.

conjugate redox pair: An electron donor and its corresponding electron acceptor form, for example, Cu^+ (donor) and Cu^{2+} (acceptor), or NADH (donor) and NAD^+ (acceptor).

consensus sequence: A DNA or amino acid sequence consisting of the residues that most commonly occur at each position in a set of similar sequences.

conservative substitution: Replacement of an amino acid residue in a polypeptide by another residue with similar properties; for example, substitution of Glu by Asp.

constitutive enzymes: Enzymes required at all times by a cell and present at some constant level; for example, many enzymes of the central metabolic pathways. Sometimes called housekeeping enzymes.

contig: A series of overlapping clones or a continuous sequence defining an uninterrupted section of a chromosome.

contour length: The length of a helical polymeric molecule as measured along its helical axis.

cooperativity: The characteristic of an enzyme or other protein in which binding of the first molecule of a ligand changes the affinity for the second molecule. In positive cooperativity, the affinity for

the second ligand molecule increases; in negative cooperativity, it decreases. cotransport: The simultaneous transport, by a single transporter, of two solutes across a membrane. See also antiport; symport. coupled reactions: Two chemical reactions that have a common intermediate and thus a means of energy transfer from one to the other. covalent bond: A chemical bond that involves sharing of electron pairs. C, plants: Plants (generally tropical) in which CO_2 is first fixed into a four-carbon compound (oxaloacetate or malate) before entering the Calvin cycle via rubisco. cristae: Infoldings of the inner mitochondrial membrane. CRP: See cAMP receptor protein. cruciform: Secondary structure in doublestranded RNA or DNA in which the double helix is denatured at palindromic repeat sequences in each strand, and each separated strand is paired internally to form opposing hairpin structures. See also hairpin. cyclic AMP (cAMP, adenosine 3', 5'-cyclic monophosphate): A second messenger; its formation in a cell by adenylyl cyclase is stimulated by certain hormones or other molecular signals. cyclic electron flow: In chloroplasts, the light-induced flow of electrons originating from and returning to photosystem I. cyclic photophosphorylation: ATP synthesis driven by cyclic electron flow through photosystem I. cyclin: One of a family of proteins that activate cyclin-dependent protein kinases and thereby regulate the cell cycle. cytochrome P-450: A family of hemecontaining enzymes, with a characteristic absorption band at 450 nm, that participate in biological hydroxylations with Os. cytochromes: Heme proteins serving as electron carriers in respiration, photosynthesis, and other oxidation-reduction reactions. cytokine: One of a family of small secreted proteins (such as interleukins or interferons) that activate cell division or differentiation by binding to plasma membrane receptors in target cells. cytokinesis: The final separation of daughter cells following mitosis. cytoplasm: The portion of a cell's contents outside the nucleus but within the plasma membrane; includes organelles such as mitochondria. cytoskeleton: The filamentous network that provides structure and organization to the cytoplasm; includes actin filaments, microtubules, and intermediate filaments. cytosol: The continuous aqueous phase of the cytoplasm, with its dissolved solutes; excludes the organelles such as mitochondria. d dalton: Unit of atomic or molecular weight; 1 dalton (Da) is the weight of a hydrogen atom (1.66×10^{-27} g). dark reactions: See carbon-assimilation reactions. deamination: The

enzymatic removal of amino groups from biomolecules such as amino acids or nucleotides. degenerate code: A code in which a single element in one language is specified by more than one element in a second language. dehydrogenases: Enzymes that catalyze the removal of pairs of hydrogen atoms from substrates. deletion mutation: A mutation resulting from the deletion of one or more nucleotides from a gene or chromosome. AG: See free-energy change. AG: See activation energy. AG[°]: See standard free-energy change. denaturation: Partial or complete unfolding of the specific native conformation of a polypeptide chain, protein, or nucleic acid such that the function of the molecule is lost. denatured protein: A protein that has lost enough of its native conformation by exposure to a destabilizing agent such as heat or detergent that its function is lost. de novo pathway: Pathway for the synthesis of a biomolecule, such as a nucleotide, from simple precursors; as distinct from a salvage pathway. deoxyribonucleic acid: See DNA. deoxyribonucleotides: Nucleotides containing 2-deoxy-p-ribose as the pentose component. desaturases: Enzymes that catalyze the introduction of double bonds into the hydrocarbon portion of fatty acids. desensitization: Universal process by which sensory mechanisms cease to respond after prolonged exposure to the specific stimulus they detect. desolvation: In aqueous solution, the release of bound water surrounding a solute. diabetes mellitus: A group of metabolic diseases with symptoms that result from a deficiency in insulin production or utilization, characterized by a failure in glucose transport from the blood into cells at normal glucose concentrations. dialysis: Removal of small molecules from a solution of a macromolecule by their diffusion through a semipermeable membrane into a suitably buffered solution. differential centrifugation: Separation of cell organelles or other particles of different size by their different rates of sedimentation in a centrifugal field. differentiation: Specialization of cell structure and function during growth and development. diffusion: The net movement of molecules in the direction of lower concentration. digestion: Enzymatic hydrolysis of major nutrients in the gastrointestinal system to yield their simpler components. diploid: Having two sets of genetic information; describes a cell with two chromosomes of each type. Compare haploid. disaccharide: A carbohydrate consisting of two covalently joined monosaccharide units. dissociation constant: An equilibrium constant (K_a) for the

dissociation of a complex of two or more biomolecules into its components;

for example, dissociation of a substrate from an enzyme.

disulfide bond: A covalent bond involving the oxidative linkage of two Cys residues, from the same or different polypeptide chains, forming a cystine residue.

DNA (deoxyribonucleic acid): A polynucleotide with a specific sequence of deoxyribonucleotide units covalently joined through 3',5'-phosphodiester bonds; serves as the carrier of genetic information.

DNA chimera: DNA containing genetic information derived from two different species.

DNA chip: Informal term for a DNA microarray, referring to the small size of typical microarrays.

DNA cloning: See cloning.

DNA library: A collection of cloned DNA fragments.

DNA ligases: Enzymes that creates a phosphodiester bond between the 3' end of one DNA segment and the 5' end of another.

DNA looping: The interaction of proteins bound at distant sites on a DNA molecule so that the intervening DNA forms a loop.

DNA microarray: A collection of DNA sequences immobilized on a solid surface, with individual sequences laid out in patterned arrays that can be probed by hybridization.

DNA polymerase: An enzyme that catalyzes template-dependent synthesis of DNA from its deoxyribonucleoside 5'-triphosphate precursors.

DNA supercoiling: The coiling of DNA upon itself, generally as a result of bending, underwinding, or overwinding of the DNA helix.

DNA transposition: See transposition.

domain: A distinct structural unit of a polypeptide; domains may have separate functions and may fold as independent, compact units.

double helix: The natural coiled conformation of two complementary, antiparallel DNA chains.

double-reciprocal plot: A plot of $1/V_o$ versus $1/[S]$, which allows a more accurate determination of V_{max} and K_m than a plot of V_p versus $[S]$; also called the Lineweaver-Burk plot.

$e E'^{\circ}$: See standard reduction potential.

ECM: See extracellular matrix.

electrochemical gradient: The resultant of the gradients of concentration and of electric charge of an ion across a membrane; the driving force for oxidative phosphorylation and photophosphorylation.

electrochemical potential: The energy required to maintain a separation of charge and of concentration across a membrane.

electrogenic: Contributing to an electrical potential across a membrane.

electron acceptor: A substance that receives electrons in an oxidation-reduction reaction.

electron carrier: A protein, such as a flavoprotein or a cytochrome, that can reversibly gain and lose electrons; functions in the transfer

of electrons from organic nutrients to oxygen or some other terminal acceptor. electron donor: A substance that donates electrons in an oxidation-reduction reaction. electron transfer: Movement of electrons from electron donor to electron acceptor; especially, from substrates to oxygen via the carriers of the respiratory (electron-transfer) chain. electrophile: An electron-deficient group with a strong tendency to accept electrons from an electron-rich group (nucleophile). electrophoresis: Movement of charged solutes in response to an electrical field; often used to separate mixtures of ions, proteins, or nucleic acids. elongation factors: (1) Proteins that function in the elongation phase of eukaryotic transcription. (2) Specific proteins required in the elongation of polypeptide chains by ribosomes. eluate: The effluent from a chromatographic column. enantiomers: Stereoisomers that are nonsuperposable mirror images of each other. endergonic reaction: A chemical reaction that consumes energy (that is, for which ΔG is positive). endocrine: Pertaining to cellular secretions that enter the bloodstream and have their effects on distant tissues. endocytosis: The uptake of extracellular material by its inclusion in a vesicle (endosome) formed by invagination of the plasma membrane. endonucleases: Enzymes that hydrolyze the interior phosphodiester bonds of a nucleic acid—that is, act at bonds other than the terminal bonds. endoplasmic reticulum: An extensive system of double membranes in the cytoplasm of eukaryotic cells; it encloses secretory channels and is often studded with ribosomes (rough endoplasmic reticulum). endothermic reaction: A chemical reaction that takes up heat (that is, for which ΔH is positive). end-product inhibition: See feedback inhibition. enhancers: DNA sequences that facilitate the expression of a given gene; may be located a few hundred, or even thousand, base pairs away from the gene. enthalpy (H): The heat content of a system. enthalpy change (ΔH): For a reaction, approximately equal to the difference between the energy used to break bonds and the energy gained by the formation of new ones. entropy (S): The extent of randomness or disorder in a system. enzyme: A biomolecule, either protein or RNA, that catalyzes a specific chemical reaction. It does not affect the equilibrium of the catalyzed reaction; it enhances the rate of the reaction by providing a reaction path with a lower activation energy. enzyme cascade: A series of reactions, often involved in regulatory events, in which one G-5 Glossary enzyme activates

another (often by phosphorylation), which activates a third, and so on. The effect of a catalyst activating a catalyst is a large amplification of the signal that initiated the cascade.

epigenetic: Describes any inherited characteristic of a living organism that is acquired by means that do not involve the nucleotide sequence of the parental chromosomes; for example, covalent modifications of histones.

epimerases: Enzymes that catalyze the reversible interconversion of two epimers.

epimers: Two stereoisomers differing in configuration at one asymmetric center in a compound having two or more asymmetric centers.

epithelial cell: Any cell that forms part of the outer covering of an organism or organ.

epitope: An antigenic determinant; the particular chemical group or groups in a macromolecule (antigen) to which a given antibody binds.

epitope tag: A protein sequence or domain bound by some well-characterized antibody.

equilibrium: The state of a system in which no further net change is occurring; the free energy is at a minimum.

equilibrium constant (K_{eq}): A constant, characteristic for each chemical reaction, that relates the specific concentrations of all reactants and products at equilibrium at a given temperature and pressure.

erythrocyte: A cell containing large amounts of hemoglobin and specialized for oxygen transport; a red blood cell.

essential amino acids: Amino acids that cannot be synthesized by humans (and other vertebrates) and must be obtained from the diet.

essential fatty acids: The group of polyunsaturated fatty acids produced by plants, but not by humans; required in the human diet.

ethanol fermentation: The anaerobic conversion of glucose to ethanol via glycolysis; also called alcohol fermentation. See also fermentation.

euchromatin: The regions of interphase chromosomes that stain diffusely, as opposed to the more condensed, heavily staining, heterochromatin. These are often regions in which genes are being actively expressed.

eukaryote: A unicellular or multicellular organism with cells having a membrane-bounded nucleus, multiple chromosomes, and internal organelles.

excited state: An energy-rich state of an atom or molecule, produced by the absorption of light energy; as distinct from ground state.

exergonic reaction: A chemical reaction that proceeds with the release of free energy (that is, for which ΔG is negative).

exocytosis: The fusion of an intracellular vesicle with the plasma membrane, releasing the vesicle contents to the extracellular space.

exon: The segment of a eukaryotic gene that encodes a portion of the final product of the

gene; a segment of RNA that remains after posttranscriptional processing and is

G-6 Glossary transcribed into a protein or incorporated into the structure of an RNA. See also intron. exonucleases: Enzymes that hydrolyze only those phosphodiester bonds that are in the terminal positions of a nucleic acid. exothermic reaction: A chemical reaction that releases heat (that is, for which ΔH is negative). expression vector: See vector. extracellular matrix (ECM): An interwoven combination of glycosaminoglycans, proteoglycans, and proteins, just outside the plasma membrane, that provides cell anchorage, positional recognition, and traction during cell migration. extrahepatic: Describes all tissues outside the liver; implies the centrality of the liver in metabolism. facilitated diffusion: See passive transport. FAD (flavin adenine dinucleotide): The coenzyme of some oxidation-reduction enzymes; contains riboflavin. F₁ ATPase: The multiprotein subunit of ATP synthase that has the ATP-synthesizing catalytic sites. It interacts with the F₀ subunit of ATP synthase, coupling proton movement to ATP synthesis. fatty acid: A long-chain aliphatic carboxylic acid found in natural fats and oils; also a component of membrane phospholipids and glycolipids. feedback inhibition: Inhibition of an allosteric enzyme at the beginning of a metabolic sequence by the end product of the sequence; also known as end-product inhibition. fermentation: Energy-yielding anaerobic breakdown of a nutrient molecule, such as glucose, without net oxidation; yields lactate, ethanol, or some other simple product. fibrin: A protein factor that forms the crosslinked fibers in blood clots. fibrinogen: The inactive precursor protein of fibrin. fibroblast: A cell of the connective tissue that secretes connective tissue proteins such as collagen. fibrous proteins: Insoluble proteins that serve a protective or structural role; contain polypeptide chains that generally share a common secondary structure. first law of thermodynamics: The law stating that, in all processes, the total energy of the universe remains constant. Fischer projection formulas: A method for representing molecules that shows the configuration of groups around chiral centers; also known as projection formulas. 5' end: The end of a nucleic acid that lacks a nucleotide bound at the 5' position of the terminal residue. flagellum: A cell appendage used in propulsion. Bacterial flagella have a much simpler structure than eukaryotic flagella, which are similar to cilia. flavin-linked dehydrogenases: Dehydrogenases requiring one of the riboflavin coenzymes, FMN or

FAD. flavin nucleotides: Nucleotide coenzymes (FMN and FAD) containing riboflavin. flavoprotein: An enzyme containing a flavin nucleotide as a tightly bound prosthetic group. flippases: Membrane proteins in the ABC transporter family that catalyze the movement of phospholipids from the extracellular leaflet to the cytosolic leaflet of a membrane bilayer. floppases: Membrane proteins in the ABC transporter family that catalyze movement of phospholipids from the cytosolic leaflet to the extracellular leaflet of a membrane bilayer. fluid mosaic model: A model describing biological membranes as a fluid lipid bilayer with embedded proteins; the bilayer exhibits both structural and functional asymmetry. fluorescence: Emission of light by excited molecules as they revert to the ground state. fluorescence recovery after photobleaching: See FRAP. fluorescence resonance energy transfer: See FRET. FMN (flavin mononucleotide): Riboflavin phosphate, a coenzyme of certain oxidation-reduction enzymes. fold: See motif. footprinting: A technique for identifying the nucleic acid sequence bound by a DNA- or RNA-binding protein. fraction: A portion of a biological sample that has been subjected to a procedure designed to separate macromolecules based on a property such as solubility, net charge, molecular weight, or function. fractionation: The process of separating the proteins or other components of a complex molecular mixture into fractions based on differences in properties such as solubility, net charge, molecular weight, or function. frame shift: A mutation caused by insertion or deletion of one or more paired nucleotides, changing the reading frame of codons during protein synthesis; the polypeptide product has a garbled amino acid sequence beginning at the mutated codon. FRAP (fluorescence recovery after photobleaching): A technique used to quantify the diffusion of membrane components (lipids or proteins) in the plane of the bilayer. free energy (G): The component of the total energy of a system that can do work at constant temperature and pressure. free energy of activation ($\Delta G^\ddagger$): See activation energy. free-energy change (ΔG): The amount of free energy released (negative ΔG) or absorbed (positive ΔG) in a reaction at constant temperature and pressure. free radical: See radical. FRET (fluorescence resonance energy transfer): A technique for estimating the distance between two proteins or two domains of a protein by measuring the nonradiative transfer of energy between reporter chromophores when one is excited and the fluorescence emitted from the other is

quantified. functional group: The specific atom or group of atoms that confers a particular chemical property on a biomolecule. fusion protein: (1) One of a family of proteins that facilitate membrane fusion. (2) The protein product of a gene created by the fusion of two distinct genes or portions of genes. futile cycle: A cycle of enzyme-catalyzed reactions that results in release of thermal energy by the hydrolysis of ATP. G_i: See inhibitory G protein. G_s: See stimulatory G protein. gametes: Reproductive cells with a haploid gene content; sperm or egg cells. ganglioside: Sphingolipid containing a complex oligosaccharide as a head group; especially common in nervous tissue. GEFs: See guanosine nucleotide-exchange factors. gel filtration: See size-exclusion chromatography. gene: A chromosomal segment that codes for a single functional polypeptide chain or RNA molecule. gene expression: Transcription, and in the case of proteins, translation, to yield the product of a gene; a gene is expressed when its biological product is present and active. gene fusion: The enzymatic attachment of one gene, or part of a gene, to another. general acid-base catalysis: Catalysis involving proton transfer(s) to or from a molecule other than water. genetic code: The set of triplet code words in DNA (or mRNA) coding for the amino acids of proteins. genetic engineering: Any process by which genetic material, particularly DNA, is altered by a molecular biologist. genetic map: A diagram showing the relative sequence and position of specific genes along a chromosome. genome: All the genetic information encoded in a cell or virus. genomic library: A DNA library containing DNA segments that represent all (or most) of the sequences in an organism's genome. genomics: A science devoted broadly to the understanding of cellular and organism genomes. genotype: The genetic constitution of an organism, as distinct from its physical characteristics, or phenotype. geometric isomers: Isomers related by rotation about a double bond; also called cis and trans isomers. germ-line cell: A type of animal cell that is formed early in embryogenesis and may multiply by mitosis or produce by meiosis cells that develop into gametes (egg or sperm cells). GFP: See green fluorescent protein.

globular proteins: Soluble proteins with a globular (somewhat rounded) shape. glucogenic: Capable of being converted into glucose or glycogen by the process of gluconeogenesis. gluconeogenesis: The biosynthesis of a carbohydrate from simpler, noncarbohydrate precursors such as oxaloacetate or pyruvate. GLUT: Designation for a family of membrane proteins that transport glucose. glycan: A polymer of monosaccharide units joined by glycosidic bonds; polysaccharide. glyceroneogenesis: The synthesis in adipocytes of glycerol 3-phosphate from pyruvate for use in triacylglycerol synthesis. glycerophospholipid: An amphipathic lipid with a glycerol backbone; fatty acids are esterlinked to C-1 and C-2 of glycerol, and a polar alcohol is attached through a phosphodiester linkage to C-3. glycoconjugate: A compound containing a carbohydrate component bound covalently to a protein or lipid, forming a glycoprotein or glycolipid. glycogenesis: The process of converting glucose to glycogen. glycogenin: The protein that both primes the synthesis of new glycogen chains and catalyzes the polymerization of the first few sugar residues of each chain before glycogen synthase continues the extension. glycogenolysis: The enzymatic breakdown of stored (not dietary) glycogen. glycolate pathway: The metabolic pathway in photosynthetic organisms that converts glycolate produced during photorespiration into 3-phosphoglycerate. glycolipid: A lipid containing a carbohydrate group. glycolysis: The catabolic pathway by which a molecule of glucose is broken down into two molecules of pyruvate. glycome: The full complement of carbohydrates and carbohydrate-containing molecules of a cell or tissue under a particular set of conditions. glycomics: The systematic characterization of the glycome. glycoprotein: A protein containing a carbohydrate group. glycosaminoglycan: A heteropolysaccharide of two alternating units: one is either N-acetylglucosamine or N-acetylgalactosamine; the other is a uronic acid (usually glucuronic acid). Formerly called a mucopolysaccharide. glycosidic bonds: See O-glycosidic bonds. glycosphingolipid: An amphipathic lipid with a sphingosine backbone to which are attached a long-chain fatty acid and a polar alcohol. glyoxylate cycle: A variant of the citric acid cycle, for the net conversion of acetate into succinate and, eventually, new carbohydrate; present in bacteria and some plant cells. glyoxysome: A specialized peroxisome containing the enzymes of the glyoxylate

cycle; found in cells of germinating seeds. Golgi complex: A complex membranous organelle of eukaryotic cells; functions in the posttranslational modification of proteins and their secretion from the cell or incorporation into the plasma membrane or organellar membranes. GPCRs: See G protein-coupled receptors. GPI-anchored protein: A protein held to the outer monolayer of the plasma membrane by its covalent attachment through a short oligosaccharide chain to a phosphatidylinositol molecule in the membrane. G protein-coupled receptor kinases (GRKs): A family of protein kinases that phosphorylate Ser and Thr residues near the carboxyl terminus of G protein-coupled receptors, initiating their internalization. G protein-coupled receptors (GPCRs): A large family of membrane receptor proteins with seven transmembrane helical segments, often associating with G proteins to transduce an extracellular signal into a change in cellular metabolism; also called heptahelical receptors. G proteins: A large family of GTP-binding proteins that act in intracellular signaling pathways and in membrane trafficking. Active when GTP is bound, they self-inactivate by converting GTP to GDP. Also called guanosine nucleotide—binding proteins. gram molecular weight: For a compound, the weight in grams that is numerically equal to its molecular weight; the weight of one mole. grana: Stacks of thylakoids, flattened membranous sacs or disks, in chloroplasts. green fluorescent protein (GFP): A small protein from a marine organism that produces a bright fluorescence in the green region of the visible spectrum. Fusion proteins with GFP are commonly used to determine the subcellular location of the fused protein by fluorescence microscopy. ground state: The normal, stable form of an atom or molecule; as distinct from the excited state. group transfer potential: A measure of the ability of a compound to donate an activated group (such as a phosphate or acyl group); generally expressed as the standard free energy of hydrolysis. growth factors: Proteins or other molecules that act from outside a cell to stimulate cell growth and division. GTPase activator proteins (GAPs): Regulatory proteins that bind activated G proteins and stimulate their intrinsic GTPase activity, speeding their self-inactivation. guanosine nucleotide-binding proteins: See G proteins. guanosine nucleotide—exchange factors (GEFs): Regulatory proteins that bind to and activate G proteins by stimulating the exchange of bound GDP for GTP. h hairpin: Secondary structure in single-stranded RNA

or DNA, in which complementary parts of a palindromic repeat fold back and are paired G-C to form an antiparallel duplex helix that is closed at one end. half-life: The time required for the disappearance or decay of one-half of a given component in a system. haploid: Having a single set of genetic information; describes a cell with one chromosome of each type. Compare diploid. haplotype: A combination of alleles of different genes located sufficiently close together on a chromosome that they tend to be inherited together. hapten: A small molecule that, when linked to a larger molecule, elicits an immune response. Haworth perspective formulas: A method for representing cyclic chemical structures so as to define the configuration of each substituent group; commonly used for representing sugars. helicases: Enzymes that catalyze the separation of strands in a DNA molecule before replication. heme: The iron-porphyrin prosthetic group of heme proteins. heme protein: A protein containing a heme as a prosthetic group. hemoglobin: A heme protein in erythrocytes; functions in oxygen transport. Henderson-Hasselbalch equation: An equation relating the pH, the pK_a, and the ratio of the concentrations of proton-acceptor (A⁻) and proton-donor (HA) species in a solution: $\text{pH} = \text{pK}_a + \log \frac{[\text{A}^-]}{[\text{HA}]}$. heparan sulfate: A sulfated polymer of alternating N-acetylglucosamine and a uronic acid, either glucuronic or iduronic acid; typically found in the extracellular matrix. hepatocyte: The major cell type of liver tissue. heptahelical receptors: See G protein-coupled receptors. heteropolysaccharide: A polysaccharide containing more than one type of sugar. heterotroph: An organism that requires complex nutrient molecules, such as glucose, as a source of energy and carbon. heterotropic: Describes an allosteric modulator that is distinct from the normal ligand. heterotropic enzyme: An allosteric enzyme requiring a modulator other than its substrate. hexose: A simple sugar with a backbone containing six carbon atoms. hexose monophosphate pathway: See pentose phosphate pathway. high-performance liquid chromatography (HPLC): Chromatographic procedure, often conducted at relatively high pressures using automated equipment, which permits refined and highly reproducible profiles. Hill coefficient: A measure of cooperative interaction between protein subunits. Hill reaction: The evolution of oxygen and photoreduction of an artificial electron acceptor by a chloroplast preparation in the absence of carbon dioxide.

G-8 Glossary histones: The family of basic proteins that associate tightly with DNA in the chromosomes of all eukaryotic cells. Holliday intermediate: An intermediate in genetic recombination in which two doublestranded DNA molecules are joined by a reciprocal crossover involving one strand of each molecule. holoenzyme: A catalytically active enzyme, including all necessary subunits, prosthetic groups, and cofactors. homeobox: A conserved DNA sequence of 180 base pairs that encodes a protein domain found in many proteins that play a regulatory role in development. homeodomain: The protein domain encoded by the homeobox; a regulatory unit that determines the segmentation of a body plan. homeostasis: The maintenance of a dynamic steady state by regulatory mechanisms that compensate for changes in external circumstances. homeotic genes: Genes that regulate development of the pattern of segments in the *Drosophila* body plan; similar genes are found in most vertebrates. homologs: Genes or proteins that possess a clear sequence and functional relationship to each other. homologous genetic recombination: Recombination between two DNA molecules of similar sequence, occurring in all cells; occurs during meiosis and mitosis in eukaryotes. homologous proteins: Proteins having similar sequences and functions in different species; for example, the hemoglobins. homotropic: Describes an allosteric modulator that is identical to the normal ligand. homotropic enzyme: An allosteric enzyme that uses its substrate as a modulator. hormone: A chemical substance synthesized in small amounts by an endocrine tissue and carried in the blood to another tissue, where it acts as a messenger to regulate the function of the target tissue or organ. hormone receptor: A protein in, or on the surface of, target cells that binds a specific hormone and initiates the cellular response. hormone response element (HRE): A short (12 to 20 bp) DNA sequence that binds receptors for steroid, retinoid, thyroid, and vitamin D hormones, altering the expression of the contiguous genes. Each hormone has a consensus sequence preferred by the cognate receptor. HPLC: See high-performance liquid chromatography. HRE: See hormone response element. hyaluronan: A high molecular weight, acidic polysaccharide typically composed of the alternating disaccharide GlcUA(B1—3)GlcNAc; a major component of the extracellular matrix, forming larger complexes (proteoglycans) with proteins and other acidic polysaccharides. Also

called hyaluronic acid. hydrogen bond: A weak electrostatic attraction between one electronegative atom (such as oxygen or nitrogen) and a hydrogen atom covalently linked to a second electronegative atom. hydrolases: Enzymes (proteases, lipases, phosphatases, nucleases, for example) that catalyze hydrolysis reactions. hydrolysis: Cleavage of a bond, such as an anhydride or peptide bond, by the addition of the elements of water, yielding two or more products. hydronium ion: The hydrated hydrogen ion (H_3O^+). hydrophathy index: A scale that expresses the relative hydrophobic and hydrophilic tendencies of a chemical group. hydrophilic: Polar or charged; describes molecules or groups that associate with (dissolve easily in) water. hydrophobic: Nonpolar; describes molecules or groups that are insoluble in water. hydrophobic interactions: The association of nonpolar groups or compounds with each other in aqueous systems, driven by the tendency of the surrounding water molecules to seek their most stable (disordered) state. hyperchromic effect: The large increase in light absorption at 260 nm occurring as a double-helical DNA unwinds (melts). hypoxia: The metabolic condition in which the supply of oxygen is severely limited. i immune response: The capacity of a vertebrate to generate antibodies to an antigen, a macromolecule foreign to the organism. immunoblotting: A technique that employs antibodies to detect the presence of a protein in a biological sample after the proteins in the sample have been separated by gel electrophoresis, transferred to a membrane and immobilized; also called Western blotting. immunoglobulin: An antibody protein generated against, and capable of binding specifically to, an antigen. induced fit: A change in the conformation of an enzyme in response to substrate binding that renders the enzyme catalytically active; also used to denote changes in the conformation of any macromolecule in response to ligand binding such that the binding site of the macromolecule better conforms to the shape of the ligand. inducer: A signal molecule that, when bound to a regulatory protein, produces an increase in the expression of a given gene. induction: An increase in the expression of a gene in response to a change in the activity of a regulatory protein. informational macromolecules: Biomolecules containing information in the form of specific sequences of different monomers; for example, many proteins, lipids, polysaccharides, and nucleic acids. inhibitory G protein (G_i): A trimeric GTP-binding

protein that, when activated by an associated plasma membrane receptor, inhibits a neighboring membrane enzyme such as adenylyl cyclase. Compare stimulatory G protein (G_s). initiation codon: AUG (sometimes GUG or, even more rarely, UUG in bacteria and archaea); codes for the first amino acid in a polypeptide sequence: N-formylmethionine in bacteria; methionine in archaea and eukaryotes. initiation complex: A complex of a ribosome with an mRNA and the initiating Met-tRNA^{TM*} or f{Met-tRNA^{TMIII} ready for the elongation steps. inorganic pyrophosphatase: An enzyme that hydrolyzes a molecule of inorganic pyrophosphate to yield two molecules of (ortho) phosphate; also known as pyrophosphatase. insertion mutation: A mutation caused by insertion of one or more extra bases, or a mutagen, between successive bases in DNA. insertion sequence: Specific base sequences at either end of a transposable segment of DNA. in situ: "In position"; that is, in its natural position or location. integral proteins: Proteins firmly bound to a membrane by hydrophobic interactions; as distinct from peripheral proteins. integrin: One of a large family of heterodimeric transmembrane proteins that mediate adhesion of cells to other cells or to the extracellular matrix. intercalation: Insertion between stacked aromatic or planar rings; for example, the insertion of a planar molecule between two successive bases in a nucleic acid. intermediary metabolism: In cells, the enzyme-catalyzed reactions that extract chemical energy from nutrient molecules and use it to synthesize and assemble cell components. intrinsically disordered proteins: Proteins, or segments of proteins, that lack a definable three-dimensional structure in solution. intron: A sequence of nucleotides in a gene that is transcribed but excised before the gene is translated; also called intervening sequence. See also exon. in vitro: "In glass"; that is, in the test tube. in vivo: "In life"; that is, in the living cell or organism. ion channel: An integral protein that provides or the regulated transport of a specific ion, or ions, across a membrane. ion-exchange chromatography: A process or separating complex mixtures of ionic compounds by many repeated partitionings between a flowing (mobile) phase and a stationary phase consisting of a polymeric resin hat contains fixed charged groups. ionizing radiation: A type of radiation, such as x rays, that causes loss of electrons from some organic molecules, thus making them more reactive. ionophore: A compound that binds one or more metal ions and is capable of diffusing across a membrane, carrying

the bound ion.

ion product of water (K_w): The product of the concentrations of H^+ and OH^- in pure water: $K_w = [H^+][OH^-] = 1 \times 10^{-14}$ at $25^\circ C$.

iron-sulfur protein: One of a large family of electron-transfer proteins in which the electron carrier is one or more iron ions associated with two or more sulfur atoms of Cys residues or of inorganic sulfide.

isoelectric focusing: An electrophoretic method for separating macromolecules on the basis of isoelectric pH.

isoelectric pH (isoelectric point, pI): The pH at which a solute has no net electric charge and thus does not move in an electric field.

isoenzymes: See isozymes.

isomerases: Enzymes that catalyze the transformation of compounds into their positional isomers.

isomers: Any two molecules with the same molecular formula but a different arrangement of molecular groups.

isoprene: The hydrocarbon 2-methyl-2,5-butadiene, a recurring structural unit of terpenoids.

isoprenoid: Any of a large number of natural products synthesized by enzymatic polymerization of two or more isoprene units; also called terpenoid.

isozymes: Multiple forms of an enzyme that catalyze the same reaction but differ in amino acid sequence, substrate affinity, V_{max} , and/or regulatory properties; also called isoenzymes.

k ketogenic: Yielding acetyl-CoA, a precursor for ketone body formation, as a breakdown product.

ketone bodies: Acetoacetate, D-3-hydroxybutyrate, and acetone; water-soluble fuels normally exported by the liver but overproduced during fasting or in untreated diabetes mellitus.

ketose: A simple monosaccharide in which the carbonyl group is a ketone.

ketosis: A condition in which the concentration of ketone bodies in the blood, tissues, and urine is abnormally high.

kinases: Enzymes that catalyze the phosphorylation of certain molecules by ATP.

kinetics: The study of reaction rates.

Krebs cycle: See citric acid cycle.

K_1 (Keransport): A kinetic parameter for a membrane transporter analogous to the Michaelis constant, K_m , for an enzymatic reaction. The rate of substrate uptake is half-maximal when the substrate concentration equals the K_1 .

lagging strand: The DNA strand that, during replication, must be synthesized in the direction opposite to that in which the replication fork moves.

law of mass action: The law stating that the rate of any given chemical reaction is proportional to the product of the activities (or concentrations) of the reactants.

leader: A short sequence near the amino terminus of a protein or the 5' end of an RNA that has a specialized targeting or

regulatory function. leading strand: The DNA strand that, during replication, is synthesized in the same direction as the replication fork moves. leaky mutant: A mutant gene that gives rise to a product with a detectable level of biological activity. leaving group: The departing or displaced molecular group in a unimolecular elimination or bimolecular substitution reaction. lectin: A protein that binds a carbohydrate, commonly an oligosaccharide, with very high affinity and specificity, mediating cell-cell interactions. lethal mutation: A mutation that inactivates a biological function essential to the life of the cell or organism. leucine zipper: A protein structural motif involved in protein-protein interactions in many eukaryotic regulatory proteins; consists of two interacting α helices in which Leu residues in every seventh position are a prominent feature of the interacting surfaces. leukocyte: White blood cell; involved in the immune response in mammals. leukotriene: Any of a class of signaling lipids derived from arachidonate in the noncyclic pathway; modulate smooth muscle activity. ligand: A small molecule that binds specifically to a larger one; for example, a hormone is the ligand for its specific protein receptor. ligases: Enzymes that catalyze condensation reactions in which two atoms are joined using the energy of ATP or another energy-rich compound. light-dependent reactions: The reactions of photosynthesis that require light and cannot occur in the dark; also known as light reactions. Lineweaver-Burk equation: An algebraic transform of the Michaelis-Menten equation, allowing determination of V_{max} and K_m by extrapolation of $[S]$ to infinity: $1/K_m, 1/V_o, 1/V_{max}$. Linking number: The number of times one closed circular DNA strand is wound about another; the number of topological links holding the circles together. lipases: Enzymes that catalyze the hydrolysis of triacylglycerols. lipid: A small water-insoluble biomolecule generally containing fatty acids, sterols, or isoprenoid compounds. lipidome: The full complement of lipid-containing molecules in a cell, organ, or tissue under a particular set of conditions. lipidomics: The systematic characterization of the lipidome. lipoate (lipoic acid): A vitamin for some microorganisms; an intermediate carrier of hydrogen atoms and acyl groups in α -keto acid dehydrogenases. G-9 Glossary lipoprotein: A lipid-protein aggregate that serves to carry water-insoluble lipids in the blood. The protein component alone is an apolipoprotein. liposome: A small, spherical vesicle composed of a

phospholipid bilayer, forming spontaneously when phospholipids are suspended in an aqueous buffer. lyases: Enzymes that catalyze the removal of a group from a molecule to form a double bond, or the addition of a group to a double bond. lymphocytes: A subclass of leukocytes involved in the immune response. See also B lymphocytes; T lymphocytes. lysis: Destruction of a plasma membrane or (in bacteria) cell wall, releasing the cellular contents and killing the cell. lysosome: A membrane-bounded organelle of eukaryotic cells; it contains many hydrolytic enzymes and serves as a degrading and recycling center for unneeded components. macromolecule: A molecule having a molecular weight in the range of a few thousand to many millions. mass-action ratio (Q): For the reaction $aA + bB \rightleftharpoons cC + dD$, the ratio $\frac{[C]^c[D]^d}{[A]^a[B]^b}$. matrix: The space enclosed by the inner membrane of the mitochondrion. mechanistic target of rapamycin complex 1: See mTORC1. meiosis: A type of cell division in which diploid cells give rise to haploid cells destined to become gametes or spores. membrane potential (V_m): The difference in electrical potential across a biological membrane, commonly measured by the insertion of a microelectrode. Typical membrane potentials vary from -25 mV (by convention, the negative sign indicates that the inside is negative relative to the outside) to greater than -100 mV across some plant vacuolar membranes. membrane transport: Movement of a polar solute across a membrane via a specific membrane protein (a transporter). messenger RNA (mRNA): A class of RNA molecules, each of which is complementary to one strand of DNA; carries the genetic message from the chromosome to the ribosomes. metabolic control: The mechanisms by which the flux through a metabolic pathway is changed to reflect a cell's altered circumstances. metabolic regulation: The mechanisms by which a cell resists changes in the concentration of individual metabolites that would otherwise occur when metabolic control mechanisms alter the flux through a pathway. metabolic syndrome: A combination of medical conditions that together predispose to cardiovascular disease and type 2 diabetes. They include high blood pressure, high concentrations of LDL and triacylglycerol in the

G-10 Glossary blood, slightly elevated fasting blood glucose concentration, and obesity. **metabolism**: The entire set of enzymecatalyzed transformations of organic molecules in living cells; the sum of anabolism and catabolism. **metabolite**: A chemical intermediate in the enzyme-catalyzed reactions of metabolism. **metabolome**: The complete set of smallmolecule metabolites (metabolic intermediates, signals, secondary metabolites) present in a given cell or tissue under specific conditions. **metabolomics**: The systematic characterization of the metabolome of a cell or tissue. **metabolon**: A supramolecular assembly of sequential metabolic enzymes. **metalloprotein**: A protein with a metal ion as its prosthetic group. **metamerism**: Division of the body into segments, as in insects, for example. **micelle**: An aggregate of amphipathic molecules in water, with the nonpolar portions in the interior and the polar portions at the exterior surface, exposed to water. **Michaelis constant (K_m)**: The substrate concentration at which an enzyme-catalyzed reaction proceeds at one-half its maximum velocity. **Michaelis-Menten equation**: The equation describing the hyperbolic dependence of the initial reaction velocity, V_o , on substrate concentration, $[S]$, in many enzyme-catalyzed reactions: $y = \frac{V_{max}[S]}{K_m + [S]}$ **Michaelis-Menten kinetics**: A kinetic pattern in which the initial rate of an enzymecatalyzed reaction exhibits a hyperbolic dependence on substrate concentration. **microRNA**: A class of small RNA molecules (20 to 25 nucleotides after processing is complete) involved in gene silencing by inhibiting translation and/or promoting the degradation of particular mRNAs. **microsomes**: Membranous vesicles formed by fragmentation of the endoplasmic reticulum of eukaryotic cells; recovered by differential centrifugation. **miRNA**: See microRNA. **mismatch**: A base pair in a nucleic acid that cannot form a normal Watson-Crick pair. **mismatch repair**: An enzymatic system for repairing base mismatches in DNA. **mitochondrion**: Membrane-bounded organelle of eukaryotic cells; contains the enzyme systems required for the citric acid cycle, fatty acid oxidation, electron transfer, and oxidative phosphorylation. **mitosis**: In eukaryotic cells, the multistep process that results in the replication of chromosomes and cell division. **mixed-function oxygenases**: Enzymes (a monooxygenase, for example) that catalyze reactions in which two reductants—one of which is generally NADPH, the other the

substrate—are oxidized. One oxygen atom is incorporated into the product, the other is reduced to HO. These enzymes often use cytochrome P-450 to carry electrons from NADPH to Os. mixed inhibition: The reversible inhibition pattern resulting when an inhibitor molecule can bind to either the free enzyme or the enzyme-substrate complex (not necessarily with the same affinity). modulator: A metabolite that, when bound to the allosteric site of an enzyme, alters its kinetic characteristics. molar solution: One mole of solute dissolved in water to give a total volume of 1,000 mL. mole: One gram molecular weight of a compound. See also Avogadro's number. monocistronic mRNA: An mRNA that can be translated into only one protein. monoclonal antibodies: Antibodies produced by a cloned hybridoma cell, which therefore are identical and directed against the same epitope of the antigen. (Hybridoma cells are stable antibody-producing cell lines that grow well in tissue culture; created by fusing an antibody-producing B cell with a myeloma cell.) monosaccharide: A carbohydrate consisting of a single sugar unit. moonlighting enzymes: Enzymes that play two distinct roles, at least one of which is catalytic; the other may be catalytic, regulatory, or structural. motif: Any distinct folding pattern for elements of secondary structure, observed in one or more proteins. A motif can be simple or complex, and can represent all or just a small part of a polypeptide chain. Also called a fold or supersecondary structure. mRNA: See messenger RNA. mTORC1 (mechanistic target of rapamycin complex 1): A multiprotein complex of mTOR (mechanistic target of rapamycin) and several regulatory subunits, which together have activity as a Ser/Thr protein kinase. Stimulated by nutrients and energy-sufficient conditions, it triggers cell growth and proliferation. mucopolysaccharide: See glycosaminoglycan. multidrug transporters: Plasma membrane transporters in the ABC transporter family that expel several commonly used antitumor drugs, thereby interfering with antitumor therapy. multienzyme system: A group of related enzymes participating in a given metabolic pathway. mutarotation: The change in specific rotation of a pyranose or furanose sugar or glycoside accompanying the equilibration of its α - and β -anomeric forms. mutases: Enzymes that catalyze the transposition of functional groups. mutation: An inheritable change in the nucleotide sequence of a chromosome. myocyte: A muscle cell. myofibril: A unit of thick and thin filaments of muscle fibers.

myosin: A contractile protein; the major component of the thick filaments of muscle and other actin-myosin systems. NAD, NADP (nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate): Nicotinamide-containing coenzymes functioning as carriers of hydrogen atoms and electrons in some oxidation-reduction reactions. Na⁺K⁺ ATPase: The electrogenic ATP-driven active transporter in the plasma membrane of most animal cells that pumps three Na⁺ outward for every two K⁺ moved inward. native conformation: The biologically active conformation of a macromolecule. ncRNA (noncoding RNA): Any RNA that does not encode instructions for a protein product. negative cooperativity: A property of some multisubunit enzymes or proteins in which binding of a ligand or substrate to one subunit impairs binding to another subunit. negative feedback: Regulation of a biochemical pathway in which a reaction product inhibits an earlier step in the pathway. neuron: A cell of nervous tissue specialized for transmission of a nerve impulse. neurotransmitter: A low molecular weight compound (usually containing nitrogen) secreted from the axon terminal of a neuron and bound by a specific receptor on the next neuron or on a myocyte; serves to transmit a nerve impulse. nitrogenase complex: A system of enzymes capable of reducing atmospheric nitrogen to ammonia in the presence of ATP. nitrogen cycle: The cycling of various forms of biologically available nitrogen through the plant, animal, and microbial worlds, and through the atmosphere and geosphere. nitrogen fixation: Conversion of atmospheric nitrogen (N) into a reduced, biologically available form by nitrogen-fixing organisms. NMR: See nuclear magnetic resonance spectroscopy. noncoding RNA: See ncRNA. noncyclic electron flow: The light-induced flow of electrons from water to NADP⁺ in oxygen-evolving photosynthesis; involves both photosystems I and II. nonessential amino acids: Amino acids that can be made by humans and other vertebrates from simpler precursors and are thus not required in the diet. nonheme iron proteins: Proteins, usually acting in oxidation-reduction reactions, containing iron but no porphyrin groups. nonpolar: Hydrophobic; describes molecules or groups that are poorly soluble in water. nonsense codon: A codon that does not specify an amino acid, but signals the termination of a polypeptide chain.

nonsense mutation: A mutation that results in the premature termination of a polypeptide chain. nonsense suppressor: A mutation, usually in the gene for a tRNA, that causes an amino acid to be inserted into a polypeptide in response to a termination codon. nontemplate strand: See coding strand. nuclear magnetic resonance (NMR) spectroscopy: A technique that utilizes certain quantum mechanical properties of atomic nuclei to study the structure and dynamics of the molecules of which they are a part. nucleases: Enzymes that hydrolyze the internucleotide (phosphodiester) linkages of nucleic acids. nucleic acids: Biologically occurring polynucleotides in which the nucleotide residues are linked in a specific sequence by phosphodiester bonds; DNA and RNA. nucleoid: In bacteria, the nuclear zone that contains the chromosome but has no surrounding membrane. nucleolus: In eukaryotic cells, a densely staining structure in the nucleus; involved in rRNA synthesis and ribosome formation. nucleophile: An electron-rich group with a strong tendency to donate electrons to an electron-deficient nucleus (electrophile); the entering reactant in a bimolecular substitution reaction. nucleoplasm: The portion of a eukaryotic cell's contents enclosed by the nuclear membrane. nucleoside: A compound consisting of a purine or pyrimidine base covalently linked to a pentose. nucleoside diphosphate kinase: An enzyme that catalyzes the transfer of the terminal phosphate of a nucleoside 5'-triphosphate to a nucleoside 5'-diphosphate. nucleoside diphosphate sugar: A coenzymelike carrier of a sugar molecule, functioning in the enzymatic synthesis of polysaccharides and sugar derivatives. nucleoside monophosphate kinase: An enzyme that catalyzes the transfer of the terminal phosphate of ATP to a nucleoside 5'-monophosphate. nucleosome: In eukaryotes, structural unit for packaging chromatin; consists of a DNA strand wound around a histone core. nucleotide: A nucleoside phosphorylated at one of its pentose hydroxyl groups. nucleus: In eukaryotes, a membrane-bounded organelle that contains chromosomes. o O-glycosidic bonds: Bonds between a sugar and another molecule (typically an alcohol, purine, pyrimidine, or sugar) through an intervening oxygen. oligomer: A short polymer, usually of amino acids, sugars, or nucleotides; the definition of "short" is somewhat arbitrary, but usually fewer than 50 subunits. oligomeric protein: A multisubunit protein having two or more

identical polypeptide chains. oligonucleotide: A short polymer of nucleotides (usually fewer than 50). oligopeptide: A few amino acids joined by peptide bonds. oligosaccharide: Several monosaccharide groups joined by glycosidic bonds. ω oxidation: An alternative mode of fatty acid oxidation in which the initial oxidation is at the carbon most distant from the carboxyl carbon; as distinct from β oxidation. oncogene: A cancer-causing gene; any of several mutant genes that cause cells to exhibit rapid, uncontrolled proliferation. See also proto-oncogene. open reading frame (ORF): A group of contiguous nonoverlapping nucleotide codons in a DNA or RNA molecule that does not include a termination codon. open system: A system that exchanges matter and energy with its surroundings. See also system. operator: A region of DNA that interacts with a repressor protein to control the expression of a gene or group of genes. operon: A unit of genetic expression consisting of one or more related genes and the operator and promoter sequences that regulate their transcription. opsin: The protein portion of the visual pigment, which becomes rhodopsin with the addition of the chromophore retinal. optical activity: The capacity of a substance to rotate the plane of plane-polarized light. optimum pH: The characteristic pH at which an enzyme has maximal catalytic activity. orexigenic: Tending to increase appetite and food consumption. ORF: See open reading frame. organelles: Membrane-bounded structures found in eukaryotic cells; contain enzymes and other components required for specialized cell functions. origin: The nucleotide sequence or site in DNA where DNA replication is initiated. orthologs: Genes or proteins from different species that possess a clear sequence and functional relationship to each other. osmosis: Bulk flow of water through a semipermeable membrane into another aqueous compartment containing solute at a higher concentration. osmotic pressure: Pressure generated by the osmotic flow of water through a semipermeable membrane into an aqueous compartment containing solute at a higher concentration. oxidases: Enzymes that catalyze oxidation reactions in which molecular oxygen serves as the electron acceptor, but neither of the oxygen atoms is incorporated into the product. Compare oxygenases. oxidation: The loss of electrons from a compound. G-11 Glossary oxidation-reduction reaction: A reaction in which electrons are transferred from a donor to an acceptor molecule; also called a redox reaction. oxidative phosphorylation: The enzymatic

phosphorylation of ADP to ATP coupled to electron transfer from a substrate to molecular oxygen. oxidizing agent (oxidant): The acceptor of electrons in an oxidation-reduction reaction. oxygenases: Enzymes that catalyze reactions in which oxygen atoms are directly incorporated into the product, forming a hydroxyl or carboxyl group. In reactions catalyzed by a monooxygenase, only one of the two O atoms is incorporated; the other is reduced to H₂O. In reactions catalyzed by a dioxygenase, both O atoms are incorporated into the product. Compare oxidases. oxygenic photosynthesis: Light-driven ATP and NADPH synthesis in organisms that use water as the electron source, producing O₂. p
palindrome: A segment of duplex DNA in which the base sequences of the two strands exhibit twofold rotational symmetry about an axis. paradigm: In biochemistry, an experimental model or example. paralogs: Genes or proteins present in the same species that possess a clear sequence and functional relationship to each other. partition coefficient: A constant that expresses the ratio in which a given solute will be partitioned or distributed between two given immiscible liquids at equilibrium. passive transport: Diffusion of a polar substance across a biological membrane through a protein transporter; also called facilitated diffusion. pathogenic: Disease-causing. PCR: See polymerase chain reaction. PDB (Protein Data Bank): An international database (www.pdb.org) that archives the data describing the three-dimensional structure of nearly all macromolecules for which structures have been published. pentose: A simple sugar with a backbone containing five carbon atoms. pentose phosphate pathway: A pathway present in most organisms that serves to interconvert hexoses and pentoses and is a source of reducing equivalents (NADPH) and pentoses for biosynthetic processes; it begins with glucose 6-phosphate and includes 6-phosphogluconate as an intermediate. Also called the phosphogluconate pathway and the hexose monophosphate pathway. peptidases: Enzymes that hydrolyze peptide bonds. peptide: Two or more amino acids covalently joined by peptide bonds. peptide bond: A substituted amide linkage between the α -amino group of one amino acid and the α -carboxyl group of another, with the elimination of the elements of water.

G-12 Glossary

peptidoglycan: A major component of bacterial cell walls; generally consists of parallel heteropolysaccharides cross-linked by short peptides.

peptidyl transferase: The enzyme activity that synthesizes the peptide bonds of proteins;

a ribozyme, part of the rRNA of the large ribosomal subunit.

peripheral proteins: Proteins loosely or reversibly bound to a membrane by hydrogen bonds or electrostatic forces; generally water soluble once released from the membrane. Compare integral proteins.

permeases: See transporters.

peroxisome: Membrane-bounded organelle of eukaryotic cells; contains peroxide-forming and peroxide-destroying enzymes.

peroxisome proliferator-activated receptor: See PPAR.

pH: The negative logarithm of the hydrogen ion concentration of an aqueous solution.

phage: See bacteriophage.

phenotype: The observable characteristics of an organism.

phosphatases: Enzymes that cleave phosphate esters by hydrolysis, the addition of the elements of water.

phosphodiester linkage: A chemical grouping that contains two alcohols esterified to one molecule of phosphoric acid, which thus serves as a bridge between them.

phosphogluconate pathway: See pentose phosphate pathway.

phospholipid: A lipid containing one or more phosphate groups.

phosphorolysis: Cleavage of a compound with phosphate as the attacking group; analogous to hydrolysis.

phosphorylases: Enzymes that catalyze phosphorolysis.

phosphorylation: Formation of a phosphate derivative of a biomolecule, usually by enzymatic transfer of a phosphoryl group from ATP.

phosphorylation potential (AG): The actual free-energy change of ATP hydrolysis under the nonstandard conditions prevailing in a cell.

photochemical reaction center: The part of a photosynthetic complex where the energy of an absorbed photon causes charge separation, initiating electron transfer.

photon: The ultimate unit (a quantum) of light energy.

photophosphorylation: The enzymatic formation of ATP from ADP coupled to the light-dependent transfer of electrons in photosynthetic cells.

photoreduction: The light-induced reduction of an electron acceptor in photosynthetic cells.

photorespiration: Oxygen consumption occurring in illuminated temperate-zone plants, largely due to oxidation of phosphoglycolate.

photosynthesis: The use of light energy to produce carbohydrates from carbon dioxide and a reducing agent such as water. Compare oxygenic photosynthesis.

photosynthetic phosphorylation: See

photophosphorylation. photosystem: In photosynthetic cells, a functional set of light-absorbing pigments and its reaction center, where the energy of an absorbed photon is transduced into a separation of electric charges. phototroph: An organism that can use the energy of light to synthesize its own fuels from simple molecules such as carbon dioxide, oxygen, and water; as distinct from a chemotroph. pI: See isoelectric pH. pKa: The negative logarithm of an equilibrium constant. plasmalogen: A phospholipid with an alkenyl ether substituent on C-1 of glycerol. plasma membrane: The exterior membrane surrounding the cytoplasm of a cell. plasma proteins: The proteins present in blood plasma. plasmid: An extrachromosomal, independently replicating, small circular DNA molecule; commonly employed in genetic engineering. plastid: In plants, a self-replicating organelle; may differentiate into a chloroplast or amyloplast. platelets: Small, enucleated cells that initiate blood clotting; they arise from bone marrow cells called megakaryocytes. Also known as thrombocytes. pleated sheet: The side-by-side, hydrogenbonded arrangement of polypeptide chains in the extended β conformation. plectonemic: Describes a structure in a molecular polymer that has a net twisting of strands about each other in some simple and regular way. PLP: See pyridoxal phosphate. polar: Hydrophilic, or "water-loving"; describes molecules or groups that are soluble in water. polarity: (1) In chemistry, the nonuniform distribution of electrons in a molecule; polar molecules are usually soluble in water. (2) In molecular biology, the distinction between the 5' and 3' ends of nucleic acids. poly(A) tail: A length of adenosine residues added to the 3' end of many mRNAs in eukaryotes (and sometimes in bacteria). polycistronic mRNA: A contiguous mRNA with more than two genes that can be translated into proteins. polyclonal antibodies: A heterogeneous pool of antibodies produced in an animal by different B lymphocytes in response to an antigen. Different antibodies in the pool recognize different parts of the antigen. polylinker: A short, often synthetic, fragment of DNA containing recognition sequences for several restriction endonucleases. polymerase chain reaction (PCR): A repetitive laboratory procedure that results in a geometric amplification of a specific DNA sequence. polymorphic: Describes a protein for which amino acid sequence variants exist in a population of organisms, but the variations do not destroy the protein's function. polynucleotide: A covalently

linked sequence of nucleotides in which the 3' hydroxyl of the pentose of one nucleotide residue is joined by a phosphodiester bond to the 5' hydroxyl of the pentose of the next residue.

polypeptide: A long chain of amino acids linked by peptide bonds; the molecular weight is generally less than 10,000.

polyribosome: See polysome.

polysaccharide: A linear or branched polymer of monosaccharide units linked by glycosidic bonds.

polysome: A complex of an mRNA molecule and two or more ribosomes; also called polyribosome.

polyunsaturated fatty acid: See PUFA.

P/O ratio: The number of moles of ATP formed in oxidative phosphorylation per 502 reduced (thus, per pair of electrons passed to O_2). Experimental values used in this text are 2.5 for passage of electrons from NADH to O_2 , and 1.5 for passage of electrons from FADH to O_2 .

porphyria: Inherited condition resulting from the lack of one or more enzymes required to synthesize porphyrins.

porphyrin: Complex nitrogenous compound containing four substituted pyrroles covalently joined into a ring; often complexed with a central metal atom.

positive cooperativity: A property of some multisubunit enzymes or proteins in which binding of a ligand or substrate to one subunit facilitates binding to another subunit.

positive-inside rule: General observation that most plasma membrane proteins are oriented so that most of their positively charged residues (Lys and Arg) are on the cytosolic face.

posttranscriptional processing: The enzymatic processing of the primary RNA transcript to produce functional RNAs, including mRNAs, tRNAs, rRNAs, and many other classes of RNAs.

posttranslational modification: Enzymatic processing of a polypeptide chain after translation from its mRNA.

PPAR (peroxisome proliferator-activated receptor): A family of nuclear transcription factors, activated by lipidic ligands, that alter the expression of specific genes, including those encoding enzymes of lipid synthesis and breakdown.

primary structure: A description of the covalent backbone of a polymer (macromolecule), including the sequence of monomeric subunits and any interchain and intrachain covalent bonds.

primary transcript: The immediate RNA product of transcription before any posttranscriptional processing reactions.

primases: Enzymes that catalyze the formation of RNA oligonucleotides used as primers by DNA polymerases.

primer: A short oligomer (of sugars or nucleotides, for example) to which an enzyme adds additional monomeric subunits.

primer terminus: The end of a primer to which monomeric subunits are added. priming: (1) In protein phosphorylation, the phosphorylation of an amino acid residue that becomes the binding site and point of reference for phosphorylation of other residues in the same protein. (2) In DNA replication, the synthesis of a short oligonucleotide to which DNA polymerases can add additional nucleotides. primosome: An enzyme complex that synthesizes the primers required for lagging strand DNA synthesis. processivity: For any enzyme that catalyzes the synthesis of a biological polymer, the property of adding multiple subunits to the polymer without dissociating from the substrate. prochiral molecule: A symmetric molecule that can react asymmetrically with an enzyme having an asymmetric active site, generating a chiral product. projection formulas: See Fischer projection formulas. prokaryote: A term used historically to refer to any species in the kingdoms Bacteria and Archaea. The differences between bacteria (formerly referred to as "eubacteria") and archaea are sufficiently great that the inclusive term is of marginal usefulness. A tendency to use "prokaryote" when referring only to bacteria is common and misleading; "prokaryote" also implies an ancestral relationship to eukaryotes, which is incorrect. In this text, "prokaryote" and "prokaryotic" are not used. promoter: A DNA sequence at which RNA polymerase may bind, leading to initiation of transcription. proofreading: The correction of errors in the synthesis of an information-containing biopolymer by removing incorrect monomeric subunits after they have been covalently added to the growing polymer. prostaglandin: One of a class of polyunsaturated, cyclic lipids derived from arachidonate that act as paracrine hormones. prosthetic group: A metal ion or an organic compound (other than an amino acid) that is covalently bound to a protein and is essential to its activity. proteases: Enzymes that catalyze the hydrolytic cleavage of peptide bonds in proteins. proteasome: Supramolecular assembly of enzymatic complexes that function in the degradation of damaged or unneeded cellular proteins. protein: A macromolecule composed of one or more polypeptide chains, each with a characteristic sequence of amino acids linked by peptide bonds. Protein Data Bank: See PDB. protein kinases: Enzymes that transfer the terminal phosphoryl group of ATP or another nucleoside triphosphate to a Ser, Thr, Tyr, Asp, or His side chain in a target protein, thereby

regulating the activity or other properties of that protein. protein phosphatases: Enzymes that hydrolyze a phosphate ester or anhydride bond on a protein, releasing inorganic phosphate, P_i. protein targeting: The process by which newly synthesized proteins are sorted and transported to their proper locations in the cell. proteoglycan: A hybrid macromolecule consisting of a heteropolysaccharide joined to a polypeptide; the polysaccharide is the major component. proteome: The full complement of proteins expressed in a given cell, or the complete complement of proteins that can be expressed by a given genome. proteomics: Broadly, the study of the protein complement of a cell or organism. proteostasis: The maintenance of a cellular steady-state collection of proteins that are required for cell functions under a given set of conditions. protomer: A general term describing any repeated unit of one or more stably associated protein subunits in a larger protein structure. If a protomer has multiple subunits, the subunits may be identical or different. proton acceptor: An anionic compound capable of accepting a proton from a proton donor; that is, a base. proton donor: The donor of a proton in an acid-base reaction; that is, an acid. proton-motive force: The electrochemical potential inherent in a transmembrane gradient of H⁺ concentration; used in oxidative phosphorylation and photophosphorylation to drive ATP synthesis. proto-oncogene: A cellular gene, usually encoding a regulatory protein, that can be converted into an oncogene by mutation. PUFA (polyunsaturated fatty acid): A fatty acid with more than one double bond, generally nonconjugated. purine: A nitrogenous heterocyclic base found in nucleotides and nucleic acids; contains fused pyrimidine and imidazole rings. puromycin: An antibiotic that inhibits polypeptide synthesis by being incorporated into a growing polypeptide chain, causing its premature termination. pyridine nucleotide: A nucleotide coenzyme containing the pyridine derivative nicotinamide; NAD or NADP. pyridoxal phosphate (PLP): A coenzyme containing the vitamin pyridoxine (vitamin B₆); functions in reactions involving amino group transfer. pyrimidine: A nitrogenous heterocyclic base found in nucleotides and nucleic acids. pyrimidine dimer: A covalently joined dimer of two adjacent pyrimidine residues in DNA, induced by absorption of UV light; most commonly derived from two adjacent thymines (a thymine dimer). pyrophosphatase: See inorganic pyrophosphatase. q Q: See mass-action ratio. quantitative

PCR (qPCR): A PCR procedure that allows the determination of how much of the amplified template was in the original sample. quantum: The ultimate unit of energy. quaternary structure: The three-dimensional structure of a multisubunit protein, particularly the manner in which the subunits fit together. r racemic mixture (racemate): An equimolar mixture of the D and L stereoisomers of an optically active compound. radical: An atom or group of atoms possessing an unpaired electron; also called a free radical. radioactive isotope: An isotopic form of an element with an unstable nucleus that stabilizes itself by emitting ionizing radiation. radioimmunoassay (RIA): A sensitive, quantitative method for detecting trace amounts of a biomolecule, based on its capacity to displace a radioactive form of the molecule from combination with its specific antibody. Ras superfamily of G proteins: Small (M, ~20,000), monomeric guanosine nucleotide-binding proteins that regulate signaling and membrane trafficking pathways. Inactive with GDP bound, they are activated by displacement of GDP by GTP, then inactivated by their intrinsic GTPase. Also called small G proteins. rate constant: The proportionality constant that relates the velocity of a chemical reaction to the concentration(s) of the reactant(s). rate-limiting step: (1) Generally, the step in an enzymatic reaction with the greatest activation energy or the transition state of highest free energy. (2) The slowest step in a metabolic pathway. reaction intermediate: Any chemical species in a reaction pathway that has a finite chemical lifetime. reactive oxygen species (ROS): Highly reactive products of the partial reduction of O₂, including hydrogen peroxide (H₂O₂), superoxide ("O₂⁻), and hydroxyl free radical "OH, produced as minor byproducts during oxidative phosphorylation. reading frame: A contiguous, nonoverlapping set of three-nucleotide codons in DNA or RNA. receptor Tyr kinase (RTK): A large family of plasma membrane proteins with ligand-binding sites on the extracellular domain, a single transmembrane helix, and a cytoplasmic domain with protein Tyr kinase activity controlled by the extracellular ligand. recombinant DNA: DNA formed by the joining of genes into new combinations. recombination: Any enzymatic process by which the linear arrangement of nucleic acid sequences in a chromosome is altered by cleavage and rejoining. recombinational DNA repair: Recombinational processes directed at the repair of DNA strand breaks or cross-links, especially at inactivated replication forks.

G-14 Glossary redox pair: An electron donor and its corresponding oxidized form; for example, NADH and NAD^{*}. redox reaction: See oxidation-reduction reaction. reducing agent (reductant): The electron donor in an oxidation-reduction reaction. reducing end: The end of a polysaccharide having a terminal sugar with a free anomeric carbon; the terminal residue can act as a reducing sugar. reducing equivalent: A general term for an electron or an electron equivalent in the form of a hydrogen atom or a hydride ion. reducing sugar: A sugar in which the carbonyl (anomeric) carbon is not involved in a glycosidic bond and can therefore undergo oxidation. reduction: The gain of electrons by a compound or ion. regulator of G protein signaling (RGS): Protein structural domain that stimulates the GTPase activity of heterotrimeric G proteins. regulatory cascade: A multistep regulatory pathway in which a signal leads to activation of a series of proteins in succession, with each protein in the succession catalytically activating the next, such that the original signal is amplified exponentially. regulatory enzyme: An enzyme with a regulatory function, through its capacity to undergo a change in catalytic activity by allosteric mechanisms or by covalent modification. regulatory gene: A gene that gives rise to a product involved in the regulation of the expression of another gene; for example, a gene encoding a repressor protein. regulatory sequence: A DNA sequence involved in regulating the expression of a gene; for example, a promoter or operator. regulon: A group of genes or operons that are coordinately regulated even though some, or all, may be spatially distant in the chromosome or genome. relaxed DNA: Any DNA that exists in its most stable and unstrained structure, typically the B form under most cellular conditions. release factors: Protein factors of the cytosol required for the release of a completed polypeptide chain from a ribosome; also known as termination factors. renaturation: Refolding of an unfolded (denatured) globular protein so as to restore its native structure and function. replication: Synthesis of daughter nucleic acid molecules identical to the parental nucleic acid. replication fork: The Y-shaped structure generally found at the point where DNA is being synthesized. replicative form: Any of the full-length structural forms of a viral chromosome that serve as distinct replication intermediates. replisome: The multiprotein complex that promotes

DNA synthesis at the replication fork. repressible enzyme: In bacteria, an enzyme whose synthesis is inhibited when its reaction product is readily available to the cell. repression: A decrease in the expression of a gene in response to a change in the activity of a regulatory protein. repressor: The protein that binds to the regulatory sequence or operator for a gene, blocking its transcription. residue: A single unit in a polymer; for example, an amino acid in a polypeptide chain. The term reflects the fact that sugars, nucleotides, and amino acids lose a few atoms (generally the elements of water) when incorporated in their respective polymers. respiration: Any metabolic process that leads to the uptake of oxygen and the release of CO₂. respiration-linked phosphorylation: ATP formation from ADP and P_i, driven by electron flow through a series of membrane-bound carriers, with a proton gradient as the direct source of energy driving rotational catalysis by ATP synthase. respiratory chain: The electron-transfer chain; a sequence of electron-carrying proteins that transfers electrons from substrates to molecular oxygen in aerobic cells. response element: A region of DNA, near (upstream from) a gene, that is bound by specific proteins that influence the rate of transcription of the gene. restriction endonucleases: Site-specific endodeoxyribonucleases that cleave both strands of DNA at points in or near the specific site recognized by the enzyme; important tools in genetic engineering. restriction fragment: A segment of doublestranded DNA produced by the action of a restriction endonuclease on a larger DNA. retinal: A 20-carbon isoprene aldehyde derived from carotene, which serves as the light-sensitive component of the visual pigment rhodopsin. Illumination converts 11-cis-retinal to all-trans-retinal. retrovirus: An RNA virus containing a reverse transcriptase. reverse transcriptase: An RNA-directed DNA polymerase in retroviruses; capable of making DNA complementary to an RNA. reversible inhibition: Inhibition by a molecule that binds reversibly to the enzyme, such that the enzyme activity returns when the inhibitor is no longer present. R group: (1) Formally, an abbreviation denoting any alkyl group. (2) Occasionally, used in a more general sense to denote virtually any organic substituent (the R groups of amino acids, for example). RGS: See regulator of G protein signaling. rhodopsin: The visual pigment, composed of the protein opsin and the chromophore retinal. RIA: See radioimmunoassay. ribonuclease: A nuclease that catalyzes the hydrolysis of certain internucleotide

linkages of RNA. ribonucleic acid: See RNA. ribonucleotide: A nucleotide containing p-ribose as its pentose component. ribosomal RNA (rRNA): A class of RNA molecules serving as components of ribosomes. ribosome: A supramolecular complex of rRNAs and proteins, approximately 18 to 22 nm in diameter; the site of protein synthesis. riboswitch: A structured segment of an mRNA that binds to a specific ligand and affects the translation or processing of the mRNA. ribozymes: Ribonucleic acid molecules with catalytic activities; RNA enzymes. ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco): The enzyme that fixes inorganic CO₂ into organic form (8-phosphoglycerate) in those organisms (plants and some microorganisms) capable of CO₂ fixation. Rieske iron-sulfur protein: A type of ironsulfur protein in which two of the ligands to the central iron ion are His side chains; act in many electron-transfer sequences, including oxidative phosphorylation and photophosphorylation. RNA (ribonucleic acid): A polyribonucleotide of a specific sequence linked by successive 3',5'-phosphodiester bonds. RNA editing: Posttranscriptional modification of an mRNA that alters the meaning of one or more codons during translation. RNA polymerase: An enzyme that catalyzes the formation of RNA from ribonucleoside 5'-triphosphates, using a strand of DNA or RNA as a template. RNA splicing: Removal of introns and joining of exons in a primary transcript. ROS: See reactive oxygen species. rRNA: See ribosomal RNA. RTK: See receptor Tyr kinase. rubisco: See ribulose 1,5-bisphosphate carboxylase/oxygenase. S salvage pathway: Pathway for synthesis of a biomolecule, such as a nucleotide, from intermediates in the degradative pathway for the biomolecule; a recycling pathway, as distinct from a de novo pathway. sarcomere: A functional and structural unit of the muscle contractile system. satellite DNA: Highly repeated, nontranslated segments of DNA in eukaryotic chromosomes; most often associated with the centromeric region. Its function is unknown. Also called simple-sequence DNA. saturated fatty acid: A fatty acid containing a fully saturated alkyl chain. scaffold proteins: Noncatalytic proteins that nucleate formation of multienzyme complexes by providing two or more specific binding sites for those proteins. scramblases: Membrane proteins that catalyze the movement of phospholipids across the membrane bilayer, leading to uniform

distribution of a lipid between the two membrane leaflets. secondary metabolism: Pathways that lead to specialized products not found in every living cell. secondary structure: The local spatial arrangement of the main-chain atoms in a segment of a polypeptide chain; also applied to polynucleotide structure. second law of thermodynamics: The law stating that, in any chemical or physical process, the entropy of the universe tends to increase. second messenger: An effector molecule synthesized in a cell in response to an external signal (first messenger) such as a hormone. sedimentation coefficient: A physical constant specifying the rate of sedimentation of a particle in a centrifugal field under specified conditions. selectins: A large family of membrane proteins, lectins that bind oligosaccharides on other cells tightly and specifically and serve to carry signals across the plasma membrane. SELEX: A method for rapid experimental identification of nucleic acid sequences (usually RNA) that have particular catalytic or ligand-binding properties. sequence polymorphisms: Any alterations in genomic sequence (base-pair changes, insertions, deletions, rearrangements) that help distinguish subsets of individuals in a population or distinguish one species from another. serine proteases: One of four major classes of proteases, featuring a reaction mechanism in which an active-site Ser residue acts as a covalent catalyst. Shine-Dalgarno sequence: A sequence in an mRNA that is required for binding bacterial ribosomes. short tandem repeat (STR): A short (typically 3 to 6 bp) DNA sequence, repeated many times in tandem at a particular location in a chromosome. SH2 domain: A protein domain that binds tightly to a phosphotyrosine residue in certain proteins such as the receptor Tyr kinases, initiating the formation of a multiprotein complex that acts in a signaling pathway. shuttle vector: A recombinant DNA vector that can be replicated in two or more different host species. See also vector. sickle-cell anemia: A human disease characterized by defective hemoglobin molecules in individuals homozygous for a mutant allele coding for the B chain of hemoglobin. σ : (1) See superhelical density. (2) A subunit of the bacterial RNA polymerase that confers specificity for certain promoters; usually designated by a superscript indicating its size (for example, σ^{70} has a molecular weight of 70,000). signal sequence: An amino acid sequence, often at the amino terminus, that signals the cellular fate or destination of

a newly synthesized protein. signal transduction: The process by which an extracellular signal (chemical, mechanical, or electrical) is amplified and converted to a cellular response. silent mutation: A mutation in a gene that causes no detectable change in the biological characteristics of the gene product. simple diffusion: The movement of solute molecules across a membrane to a region of lower concentration, unassisted by a protein transporter. simple protein: A protein yielding only amino acids on hydrolysis. simple sequence DNA: See satellite DNA. single nucleotide polymorphism (SNP): A genomic base-pair change that helps distinguish one species from another or one subset of individuals in a population. site-directed mutagenesis: A set of methods used to create specific alterations in the sequence of a gene. site-specific recombination: A type of genetic recombination that occurs only at specific sequences. size-exclusion chromatography: A procedure for the separation of molecules by size, based on the capacity of porous polymers to exclude solutes above a certain size; also called gel filtration. small G proteins: See Ras superfamily of G proteins. small nuclear RNA (snRNA): A class of short RNAs, typically 100 to 200 nucleotides long, found in the nucleus and involved in the splicing of eukaryotic mRNAs. small nucleolar RNA (snoRNA): A class of short RNAs, generally 60 to 300 nucleotides long, that guide the modification of rRNAs in the nucleolus. SNP: See single nucleotide polymorphism. somatic cells: All body cells except the germline cells. SOS response: In bacteria, a coordinated induction of a variety of genes in response to high levels of DNA damage. Southern blot: A DNA hybridization procedure in which one or more specific DNA fragments are detected in a larger population by hybridization to a complementary, labeled nucleic acid probe. specific acid-base catalysis: Acid or base catalysis involving the constituents of water (hydroxide or hydronium ions). specific activity: The number of micromoles (μmol) of a substrate transformed by an enzyme preparation per minute per milligram of protein at 25°C ; a measure of enzyme purity. specificity: The ability of an enzyme or receptor to discriminate among competing substrates or ligands. specific rotation: The rotation, in degrees, of the plane of plane-polarized light (D-line of sodium) by an optically active compound at 25°C , with a specified concentration and light path. G-15 Glossary sphingolipid: An amphipathic lipid with a sphingosine backbone to which are attached a long-chain fatty acid and a polar alcohol.

spliceosome: A complex of RNAs and proteins involved in the splicing of mRNAs in eukaryotic cells. splicing: See RNA splicing. standard free-energy change (ΔG°): The free-energy change for a reaction occurring under a set of standard conditions: temperature, 298 K; pressure, 1 atm or 101.3 kPa; and all solutes at 1 M concentration. $\Delta G'^\circ$ denotes the standard free-energy change at pH 7.0 in 55.5 M water. standard reduction potential (E°): The electromotive force exhibited at an electrode by 1 M concentrations of a reducing agent and its oxidized form at 25°C and pH 7.0; a measure of the relative tendency of the reducing agent to lose electrons. statin: Any of a class of drugs used to reduce blood cholesterol in humans; act by inhibiting the enzyme HMG-CoA reductase, an early step in sterol synthesis. steady state: A nonequilibrium state of a system through which matter is flowing and in which all components remain at a constant concentration. stem cells: The common, self-regenerating cells in bone marrow that give rise to differentiated blood cells such as erythrocytes and lymphocytes. stereoisomers: Compounds that have the same composition and the same order of atomic connections but different molecular arrangements. sterol: A lipid containing the steroid nucleus. sticky ends: Two DNA ends in the same DNA molecule, or in different molecules, with short overhanging single-stranded segments that are complementary to one another, facilitating ligation of the ends; also known as cohesive ends. stimulatory G protein (G_s): A trimeric regulatory GTP-binding protein that, when activated by an associated plasma membrane receptor, stimulates a neighboring membrane enzyme such as adenylyl cyclase. Its effects oppose those of G_i . stop codons: See termination codons. STR: See short tandem repeat. stroma: The space and aqueous solution enclosed within the inner membrane of a chloroplast, not including the contents in the thylakoid membranes. structural gene: A gene coding for a protein or RNA molecule; as distinct from a regulatory gene. substitution mutation: A mutation caused by the replacement of one base by another. substrate: The specific compound acted upon by an enzyme. substrate channeling: Movement of the chemical intermediates in a series of enzymecatalyzed reactions from the active site of one enzyme to that of the next enzyme in the

G-16 Glossary pathway, without leaving the surface of a protein complex that includes both enzymes. substrate-level phosphorylation: Phosphorylation of ADP or some other nucleoside 5'-diphosphate coupled to the dehydrogenation of an organic substrate; independent of the electron-transfer chain. suicide inactivator: A relatively inert molecule that is transformed by an enzyme, at its active site, into a reactive substance that irreversibly inactivates the enzyme. sulfonylurea drugs: A group of oral medications used in the treatment of type 2 diabetes; act by closing K^+ channels in pancreatic B cells, stimulating insulin secretion. supercoil: The twisting of a helical (coiled) molecule on itself; a coiled coil. supercoiled DNA: DNA that twists upon itself because it is under- or overwound (and thereby strained) relative to B-form DNA. superhelical density (σ): In a helical molecule such as DNA, the number of supercoils (superhelical turns) relative to the number of coils (turns) in the relaxed molecule. supersecondary structure: See motif. suppressor mutation: A mutation that totally or partially restores a function lost by a primary mutation; located at a site different from the site of the primary mutation. Svedberg (S): A unit of measure of the rate at which a particle sediments in a centrifugal field. symbionts: Two or more organisms that are mutually interdependent; usually living in physical association. symport: Cotransport of solutes across a membrane in the same direction. synteny: Conserved gene order along the chromosomes of different species. synthases: Enzymes that catalyze condensation reactions in which no nucleoside triphosphate is required as an energy source. synthetases: Enzymes that catalyze condensation reactions using ATP or another nucleoside triphosphate as an energy source. system: An isolated collection of matter; all other matter in the universe apart from the system is called the surroundings. systems biology: The study of complex biochemical systems, integrating the functions of several to all of the macromolecules in a cell (RNA, DNA, proteins). t tag: An extra segment of protein that is fused via modification of its gene to a protein of interest, usually for purposes of purification. T cell: See T lymphocyte. telomere: Specialized nucleic acid structure found at the ends of linear eukaryotic chromosomes. template: A macromolecular mold or pattern for the synthesis of an informational macromolecule. template strand: A strand of nucleic acid used by a polymerase as a template to

synthesize a complementary strand, as distinct from the coding strand. terminal transferase: An enzyme that catalyzes the addition of nucleotide residues of a single kind to the 3' end of DNA chains. termination codons: UAA, UAG, and UGA; in protein synthesis, these codons signal the termination of a polypeptide chain. Also known as stop codons. termination factors: See release factors. termination sequence: A DNA sequence, at the end of a transcriptional unit, that signals the end of transcription. tertiary structure: The three-dimensional conformation of a polymer in its native folded state. tetrahydrobiopterin: The reduced coenzyme form of biopterin. tetrahydrofolate: The reduced, active coenzyme form of the vitamin folate. thermogenesis: The biological generation of heat by muscle activity (shivering), uncoupled oxidative phosphorylation, or the operation of futile cycles. thermogenin: A protein of the inner mitochondrial membrane in brown adipose tissue that allows transmembrane movement of protons, short-circuiting the normal use of protons to drive ATP synthesis and dissipating the energy of substrate oxidation as heat; also called uncoupling protein 1 (UCP1). thiamine pyrophosphate (TPP): The active coenzyme form of vitamin B₆; involved in aldehyde transfer reactions. thioester: An ester of a carboxylic acid with a thiol or mercaptan. 3' end: The end of a nucleic acid that lacks a nucleotide bound at the 3' position of the terminal residue. thrombocytes: See platelets. thromboxane: Any of a class of molecules derived from arachidonate and involved in platelet aggregation during blood clotting. thylakoid: Closed cisterna, or disk, formed by the pigment-bearing internal membranes of chloroplasts. thymine dimer: See pyrimidine dimer. tissue culture: Method by which cells derived from multicellular organisms are grown in liquid media. titration curve: A plot of pH versus the equivalents of base added during titration of an acid. T lymphocyte (T cell): One of a class of blood cells (lymphocytes) of thymic origin, involved in cell-mediated immune reactions. tocopherol: Any of several forms of vitamin E. topoisomerases: Enzymes that introduce positive or negative supercoils in closed, circular duplex DNA. topoisomers: Different forms of a covalently closed, circular DNA molecule that differ only in their linking number. topology: The study of the properties of an object that do not change under continuous deformations such as twisting or bending. TPP: See thiamine pyrophosphate. trace element: A chemical element required by an organism in only trace

amounts. transaminases: See aminotransferases. transamination: Enzymatic transfer of an amino group from an α -amino acid to an α -keto acid. transcription: The enzymatic process whereby the genetic information contained in one strand of DNA is used to specify a complementary sequence of bases in an mRNA chain. transcriptional control: The regulation of a protein's synthesis by regulation of the formation of its mRNA. transcription factor: In eukaryotes, a protein that affects the regulation and transcription initiation of a gene by binding to a regulatory sequence near or within the gene and interacting with RNA polymerase and/or other transcription factors. transcriptome: The entire complement of RNA transcripts present in a given cell or tissue under specific conditions. transducin: The trimeric G protein activated when light is absorbed by visual rhodopsin; activated transducin activates cGMP phosphodiesterase. transduction: (1) Generally, the conversion of energy or information from one form to another. (2) The transfer of genetic information from one cell to another by means of a viral vector. transfer RNA (tRNA): A class of RNA molecules (M, 25,000 to 30,000), each of which combines covalently with a specific amino acid as the first step in protein synthesis. transformation: Introduction of an exogenous DNA into a cell, causing the cell to acquire a new phenotype. transgenic: Describes an organism that has genes from another organism incorporated in its genome as a result of recombinant DNA procedures. transition state: An activated form of a molecule in which the molecule has undergone a partial chemical reaction; the highest point on the reaction coordinate. transition-state analog: A stable molecule that resembles the transition state of a particular reaction, and therefore binds the enzyme that catalyzes the reaction more tightly than does the substrate in the ES complex. translation: The process in which the genetic information present in an mRNA molecule specifies the sequence of amino acids during protein synthesis. translational control: The regulation of a protein's synthesis by regulation of the rate of its translation on the ribosome. translational frameshifting: A programmed change in the reading frame during translation of an mRNA on a ribosome, occurring by any of several mechanisms.

translational repressor: A repressor that binds to an mRNA, blocking translation. translocase: (1) An enzyme that catalyzes membrane transport. (2) An enzyme that causes a movement such as the movement of a ribosome along an mRNA. transpiration: Passage of water from the roots of a plant to the atmosphere via the vascular system and the stomata of the leaves. transporters: Proteins that span a membrane and transport specific nutrients, metabolites, ions, or proteins across the membrane; sometimes called permeases. transposition: The movement of a gene or set of genes from one site in the genome to another. transposon (transposable element): A segment of DNA that can move from one position in the genome to another. triacylglycerol: An ester of glycerol with three molecules of fatty acid; also called a triglyceride or neutral fat. tricarboxylic acid cycle: See citric acid cycle. trimeric G proteins: Members of the G protein family with three subunits, which function in a variety of signaling pathways. Inactive with GDP bound, they are activated by associated receptors as bound GDP is displaced by GTP, then inactivated by their intrinsic GTPase activity. triose: A simple sugar with a backbone containing three carbon atoms. tRNA: See transfer RNA. tropic hormone (tropin): A peptide hormone that stimulates a specific target gland to secrete its hormone; for example, thyrotropin produced by the pituitary stimulates secretion of thyroxine by the thyroid. t-SNAREs: Protein receptors in a targeted membrane (typically the plasma membrane) that bind to v-SNAREs in the membrane of a secretory vesicle and mediate fusion of the vesicle and target membranes. tumor suppressor gene: One of a class of genes that encode proteins that normally regulate the cell cycle by suppressing cell division. Mutation of one copy of the gene is usually without effect, but when both copies are defective, the cell is allowed to continue dividing without limitation, producing a tumor. turnover number: The number of times an enzyme molecule transforms a substrate molecule per unit time, under conditions giving maximal activity at substrate concentrations that are saturating. two-component signaling systems: Signaltransducing systems found in bacteria and plants, composed of a receptor His kinase that phosphorylates an internal His residue when occupied by its ligand. It then catalyzes phosphoryl transfer to a second component, the response regulator, which, when phosphorylated, alters the output of the signaling

system. ubiquitin: A small, highly conserved eukaryotic protein that targets an intracellular protein for degradation by proteasomes. Several ubiquitin molecules are covalently attached in tandem to a Lys residue in the target protein by a specific ubiquitinating enzyme. ultraviolet (UV) radiation: Electromagnetic radiation in the region of 200 to 400 nm. uncompetitive inhibition: The reversible inhibition pattern resulting when an inhibitor molecule can bind to the enzyme-substrate complex but not to the free enzyme. uncoupling agent: A substance that uncouples phosphorylation of ADP from electron transfer; for example, 2,4-dinitrophenol. uncoupling protein 1: See thermogenin. uniport: A transport system that carries only one solute, as distinct from cotransport. unsaturated fatty acid: A fatty acid containing one or more double bonds. urea cycle: A cyclic metabolic pathway in vertebrate liver, synthesizing urea from amino groups and carbon dioxide. ureotelic: Excreting excess nitrogen in the form of urea. uricotelic: Excreting excess nitrogen in the form of urate (uric acid). v_{max} : The maximum velocity of an enzymatic reaction when the binding site is saturated with substrate. van der Waals interaction: Weak intermolecular forces between molecules as a result of each inducing polarization in the other. vector: A DNA molecule known to replicate autonomously in a host cell, to which a segment of DNA may be spliced to allow its replication; for example, a plasmid or an artificial chromosome. vectorial: Describes an enzymatic reaction or transport process in which the protein has a specific orientation in a biological membrane such that the substrate is moved from one side of the membrane to the other as it is converted into product. vectorial metabolism: Metabolic transformations in which the location (not the chemical composition) of a substrate changes relative to the plasma membrane or a membrane between two cellular compartments. Transporters catalyze vectorial reactions, as do the proton pumps of oxidative phosphorylation and photophosphorylation. vesicle: A small, spherical membranebounded particle with an internal aqueous compartment that contains components such as hormones or neurotransmitters to be moved within or out of a cell. viral vector: A viral DNA altered so that it can act as a vector for recombinant DNA. virion: A virus particle. virus: A self-replicating, infectious, nucleic acid—protein complex that requires an intact host cell for its replication; its genome is either DNA or RNA. vitamin: An

organic substance required in small quantities in the diet of some species; generally functions as a component of a coenzyme. v-SNAREs: Protein receptors in the membrane of a secretory vesicle (typically the plasma membrane) that bind to t-SNAREs in a targeted membrane (typically the plasma membrane) of a secretory vesicle and mediate fusion of the vesicle and target membranes. w Western blotting: See immunoblotting. white adipose tissue (WAT): Nonthermogenic adipose tissue rich in triacylglycerols stored and mobilized in response to hormonal signals. Transfer of electrons in the mitochondrial respiratory chain is tightly coupled to ATP synthesis. Compare brown adipose tissue. wild type: The normal (unmutated) genotype or phenotype. wobble: The relatively loose base pairing between the base at the 3' end of a codon and the complementary base at the 5' end of the anticodon. X x-ray crystallography: The analysis of x-ray diffraction patterns of a crystalline compound, used to determine the molecule's three-dimensional structure. zinc finger: A specialized protein motif involved in DNA recognition by some DNA-binding proteins; characterized by a single atom of zinc coordinated to four Cys residues or to two His and two Cys residues. Z scheme: The path of electrons in oxygenic photosynthesis from water through photosystem II and the cytochrome b_6f complex to photosystem I and finally to NADPH. When the sequence of electron carriers is plotted against their reduction potentials, the path of electrons looks like a sideways Z. zwitterion: A dipolar ion with spatially separated positive and negative charges. zymogen: An inactive precursor of an enzyme; for example, pepsinogen, the precursor of pepsin.

On the front cover The network of interactions in an animal mitochondrion. Each dot represents a compound, and each line, an enzyme that interconverts the two compounds. The major nodes include ADP, ATP, NAD^+ , and NADH. The image was constructed with Cytoscape software by Anthony Smith in the laboratory of Alan Robinson, Medical Research Council Mitochondrial Biology Unit, Cambridge, UK, using data from MitoMiner (Smith, A.C., Blackshaw, J.A., & Robinson, A.J. (2012) MitoMiner: a data warehouse for mitochondrial proteomics data. *Nucleic Acids Res.* 40, D1160-D1167). Background image: Transmission electron micrograph of interscapular brown adipose cell from a bat. Don W.
